HYDROPHOBIA

Ὑδροφοβίαν Græci appellant: miserrimum genus morbi.

ONCE more M. Pasteur is attracting the attention of the civilised world by his brilliant investigations. The disease which he hopes to prevent and ultimately to erase from the records of human misery is happily rare, but those who have watched it know that it is one of the most terrible in its effects, and that it is incurable by any means at present known. So strange are its symptoms and its course, that it has been asserted to be no real malady but a mere result of fright and superstition.[1] But of its reality there is unhappily no room for serious question.

It never arises of itself. Like small-pox and syphilis, it is always the result of contagion, and the method and conditions of its transference from rabid dogs or other animals to man are well known. Hitherto the only chance, when a human being has been bitten by a mad dog, has been to remove or isolate or destroy the virus by suction, or ligature, or cautery. And it has been doubted whether these methods are really successful even when the disease does not manifest itself afterwards. For there is often reasonable doubt as to the nature of the disease in the biter. All vicious dogs are not "mad," and all mad dogs are not truly rabid. And when, as often happens, the dog has been at once destroyed, it is impossible to supply deficiencies of previous observation. Moreover, when bitten by a rabid dog, the sufferer may yet escape, for the teeth may only have grazed the skin, and not penetrated to the living tissues beneath, or the poisonous saliva may have been mechanically wiped off by the clothing which the teeth have pierced. As with the venom of snakes, so with the saliva of rabid dogs: it is not enough for it to be spread over the skin, for that will not absorb it, nor even to be swallowed and taken into the stomach, for there, as physiologists say, it is still "outside the body," and, before it can be absorbed, undergoes such changes by the process of digestion, as kill the germs or decompose the chemical compound. The virus must be introduced into the living tissues before it can be carried over the whole body by the channels of the lymph and blood, and reach the central nervous system, on which it exerts its characteristic poisonous action. But, when once so introduced, there is every reason to believe that the terrible effects are constant and uniform. The state of the receiver of the venom at the time may probably modify the rapidity of absorption, as is the case with stimulants and with poisonous drugs; but so far as we know there is no power in the most healthy organism by which the subtle venom, once absorbed, can be neutralised or thrown out. The methods above mentioned[1]—suction by the mouth or by cupping glasses, ligature, and caustics or the actual cautery—all aim at getting the poison out before it has been absorbed. Often they come too late, often they are impracticable or ineffectual from the first. However long the time of "incubation" may be, the interval between the reception of the virus and its spread over the body, no method of preventing the terrible result is known. The length of incubation is far longer than it is in the case of small-pox, of cow-pox, of syphilis, and other known contagions. In two-thirds of the cases collected by Prof. Bollinger, of Munich, the interval of incubation was under two months; and probably it never extends to so long a period as was formerly supposed. The length of this period makes it almost certain that we have to do, not with a mere chemical compound, as in the case of subcutaneous injection of morphia, and probably of the cobra-poison, but with a "particulate contagium," like that of small-pox and chicken-pox, with a living and growing organism, like those of relapsing fever and of anthrax.

Whatever the conclusions to which pathologists will at last be led on these points, the important fact remains that there is an interval of days or months in which the latent plague, established in the patient's body, but not yet ripe for mischief, may be attacked.

[1] So, in the last century, Sir Isaac Pennington, Regius Professor of Physic at Cambridge, and in recent times Prof. Mashka, of Prague.

[1] These are what were known to the ancients:—"Si rabiosus canis est, cucurbitulâ virus ejus extrahendum est. Deinde . . . vulnus adurendum est." Celsus de Medicinâ, lib. v. cap. xxvii. § 2.

Experience has shown that it cannot be mechanically removed by any surgical operation, nor chemically neutralised or destroyed by any drug. The only promising path of investigation is to seek for some method of forestalling the action of the virus by rendering the organism unfit for its action, as patriots have ravaged their fields and burnt their towns to save their country from an invading army.

By this method Jenner robbed small-pox of most of its terror and almost all its danger, so that where Jennerian vaccination is thoroughly carried out, as in the German army and in Ireland, small-pox is practically extinct.

Pasteur's method of dealing with hydrophobia is avowedly based on the practice of vaccination; but it is not the mere introduction of the poison in a way that makes its effects less dangerous, like the inoculation of small-pox practised in the last century. Nor is it exactly analogous to Jenner's vaccination, although that term is appropriated by Pasteur himself. For in vaccination an allied disease (or possibly small-pox itself, greatly modified by long transmission through other organisms) is inoculated. In either case the course and symptoms of cow-pox are distinct from those of the more serious disease against which it protects. But in the case of hydrophobia, as in that of "chicken-plague" and anthrax, the poison of the same disease is transmitted through a succession of "bearers" until it is so modified that it may be safely inoculated, and thus the altered virus protects from that which is unmodified.

The "bearers" chosen for these experiments were rabbits. The test of the result was made, not upon human beings but upon dogs, for M. Pasteur is a philanthropist first and a zoophilist after. Fifty dogs were inoculated with modified virus obtained from the bodies[1] of rabbits which had themselves been affected with rabies by inoculation. Would a dog thus inoculated show the ordinary symptoms of the disease? Would it, if bitten by a rabid dog, or designedly inoculated with the unmodified venom of rabies, be protected? Would it, if infected with the modified virus after such direct inoculation, still be safe from its effects? The results have, so far, proved the affirmative to each of these questions. None of the "vaccinated" dogs showed signs of the dreaded disease.

Then came two cases of human beings bitten by mad dogs who were sent up to M. Pasteur in Paris from their homes in Alsace. One of them, a grocer named Vone (? Wohn), had escaped without rupture of the skin, and was sent home with the comfortable assurance that he had never been infected with the disease. The other, a boy of nine years old, had been terribly worried on the 4th of last July; not only bitten in parts covered by his clothes but also on the hands. He was rescued covered with foam, and bleeding from no less than fourteen wounds. There was no question that the dog was mad, and in all human probability this child, Joseph Meister, was doomed to a certain and horrible death. Such was the opinion of the eminent pathologist, M. Vulpian, and he was supported in this judgment by Dr. Grancher.

Under these circumstances M. Pasteur felt himself justified in applying the means to this suffering fellow-creature, which had already proved efficacious in the case of brutes.[1]

[1] Not the marrow, as the *Times* states, but the spinal cord, *moelle épinière*.

The inoculations were made with a subcutaneous needle, began on the 7th, and were concluded on the 16th of July. "Control experiments" were made with the same injections upon rabbits, and proved that the virus was active. Moreover, since the effects of the modified virus, when introduced into an unprotected animal, are rapid and severe, and its period of incubation extremely short, the result of the attempt to rescue the child from a horrible death would soon be apparent. If he had died of hydrophobia, it would probably have been within a month. If he survived this period there was every reason to hope that he would be as much protected against its future manifestation as the dogs which had been tested before.

Joseph Meister was in perfect health at the end of August, at the end of September, and at the end of October. M. Pasteur believes that he is safe from hydrophobia for the rest of his life.

If similar cases should be followed by similar results, medical science has for the first time a method of combating a frightful and incurable disease.[2] But beyond this, by inoculating dogs, as infants should be vaccinated, they will be rendered insusceptible to rabies. Any mad dog will be destroyed, and the dogs he has bitten will escape. Thus the disease may, it is hoped, be extirpated altogether.

These, however, are but hopes; at present the whole question is *sub judice*. Other competent observers must repeat the experiments, and every result must be submitted to searching criticism. This is no slight on M. Pasteur, it is only worthy respect to his genius and his skill. For the credentials of the champion who has undertaken the task of ridding the world of this horrible plague of hydrophobia are well known.

M. Louis Pasteur won his spurs as a chemist. It was his discovery of remarkable forms of crystallisation of racemic acid which first made his name known, and which gave M. Renan the opportunity for the exquisite raillery with which the man of letters welcomed the man of science to the Academy.

In dealing with the disease of silk-worms in the south of France, Pasteur first handled a physiological problem, and his thoroughness of research, fertility of resource, and felicity in experiments ended in the best result—practical success as the result of strictly scientific investigation.

Pasteur subsequently investigated the so-called cholera of domestic fowls, and by the method of "attenuated" inoculation has succeeded in protecting them from a destructive epidemic.

His far larger and more important work on the prevention of splenic fever (*charbon* or *anthrax*), the most destructive plague among cattle, has had important and useful results. It has in all probability saved countless multitudes of sheep and oxen in France. In Algeria the results were less satisfactory, and also in Hungary. On the other hand Dr. Roy found the method valuable in La

[1] "La mort de cet enfant paraissant inévitable, je me décidai, non sans de vives et cruelles inquiétudes, on doit bien le penser, à tenter sur Joseph Meister, la méthode qui m'avait constamment réussi chez les chiens" (*Comptes Rendus* de l'Académie des Sciences, October 26, 1885).

[2] One other patient, a shepherd boy, who was bitten while gallantly attacking a rabid dog, has been inoculated, and the result is to be seen.

Plata. The results of Pasteur's experiments on "pig-typhoid" have also been criticised, and not without reason, by Prof. Klein. It is foolish for newspaper correspondents to attribute hesitation in accepting scientific results to jealousy. Much scrutiny will be necessary. Adverse criticism will be welcomed. M. Pasteur's fame stands in no need of artificial protection.

His past achievements are great: his last attempt was prudent in conception, and carried out with untiring zeal and admirable care. It deserves to succeed. If so, he will again receive the applause of the civilised world; if not, he will have the sympathy and respect of every pathologist.

It is melancholy to reflect that it would be practically impossible for any duly qualified man in England to repeat, to confirm, or to correct his results. We must wait till a wiser and more humane public opinion repeals the present restrictions upon investigations like Pasteur's.

TOPINARD'S "GENERAL ANTHROPOLOGY"

Éléments d'Anthropologie générale. Par le Dr. Paul Topinard. (Paris: A. Delahaye et É. Lecrosnier, 1885.)

THE study of anthropology has been pursued, especially of late years, with great zeal by many leading *savants*, both in the Old and New World, and many valuable contributions to our knowledge have been made in all departments included under its extensive range. This is more particularly the case with respect to that part of the subject which deals with the anatomical characters of the human body. Until this branch of anthropology was so vigorously and successfully studied by Broca, complete ignorance of many fundamental questions prevailed. The direct result of the work of that great anthropologist was immense, while the indirect result due to the incentive which he gave to the study of anthropology generally cannot be over-estimated, but may be inferred from the numerous societies devoted to its study which have rapidly sprung up in various countries. Broca must be considered the great pioneer of modern anthropology, but his untimely death left his work by no means complete, and many extensive fields remained almost untrodden by the foot of the investigator. By the accumulated observations of his followers these deficiencies have been in great part made good, and the time had arrived when it was possible to form generalisations from sufficient data, and when a comprehensive work embracing the whole subject was urgently needed. For the production of such a work no one more highly fitted could be found than Prof. Paul Topinard, trained at the feet of the great master himself, possessed of an extensive knowledge of his subject, and intimately acquainted, by personal visits to the chief centres of anthropological research, with the methods employed by his contemporaries.

The volume before us deals with the elements of general anthropology, and is the first part of Prof. Topinard's contemplated work, which, when completed, will consist of three parts, the second and third parts being devoted to special anthropology and a general survey of the whole subject, concluding with man's place in time, his origin and future.

Prof. Topinard begins by giving an historical account of the origin and development of anthropology, and claims that it is not a new science developed during the latter half of the present century, but that it has, during the last twenty years, attained its adult age and gained its independence.

He divides its history into different periods: (1) from antiquity till the year 1230, the date of the birth of human anatomy; (2) from 1230–1800, when anthropology asserted itself under the influence of Buffon, Blumenbach, Sœmmering, and White; (3) from 1800–1860, during which time three important events occurred that materially assisted its development—viz. the founding of the Society of Anthropology of Paris, the demonstration of the high antiquity of man, and the promulgation of the doctrine of evolution by Darwin. To these a 4th and more recent period is added—viz. that during which Broca's personal influence, aided by the advance of natural sciences, gave great impulse to anthropology. Each of these periods is considered in detail, and many matters of much interest are discussed.

Chapters VII. and VIII. are devoted to generalities including under this a definition of anthropology, its object and the subjects which it embraces. Anthropology is defined as the branch of natural history which treats of man and of the human race. It includes two distinct departments of study—viz. anthropology proper and ethnography; the former treating of the human species and its varieties or races from a purely animal aspect, and therefore essentially anatomical and physiological in its nature; the latter dealing with people and intimately connected with sociology. For the study of anthropology proper, anatomical and zoological knowledge is essential; but such knowledge is not necessary for the study of ethnography, as questions of race are excluded from it. Having discussed the various essential and accessory anthropological sciences, the place of anthropology in science, the meaning of the terms, "characters," "types," "races," "people," "nationalities," &c., he proceeds in the ninth chapter to consider general methods of anthropological research. The different kinds of physical characters and their study are first discussed. These are of three kinds—morphological and anatomical, descriptive and anthropometrical, and finally zoological and anthropological. After a few remarks on anthropometry, and on the comparison of measurement on the skeleton and on the living, which are stated to be not generally directly comparable, an observation which entirely agrees with our own experience, the subject of craniology is discussed, the various points on the skull to which it has been found convenient to give technical names are defined, and derivations and meanings of various terms such as "brachycephalic," &c., applied to skulls to express their form, are explained. In discussing the merits of instruments for measuring the skull, their simplicity is insisted upon. The elaborate instruments used in Germany, and by those who follow the German school (of which happily there are few) are very justly condemned. Broca's *compas d'épaisseur* and the *compas glissière* are figured and recommended. These are certainly simple, but, after considerable experience in their use, we rather take exception to the former, as not being very exact, on account of the measurements being read off on a scale reduced to one-half the actual length of the measurement. This may be avoided by using Flower's craniometer, which has the further advantage that it combines both Broca's instruments in one.

The consideration of the characters used in the classification of races is begun in the tenth chapter. The first of these discussed is the hair. A very concise *résumé* is given of the anatomy of the hair follicles and the development of hair, its distribution, size and form in various races. Six types of hair are described, and good illustrations of each are given. The characters of the nose are next considered. The anatomy of the soft and hard parts forming it are described and illustrated by means of beautifully executed woodcuts. The nasal indices of the skulls of various races are tabulated, and show clearly the value of the form of the nasal opening as a race character. In the living subject eight forms of nose are recognised and figured. All of these are easily distinguishable, and we would suggest the desirability of having cards with these forms printed separately for the use of travellers as a means of obtaining much more accurate information than we now obtain from descriptions of this part of the face, which are very frequently extremely vague and unsatisfactory. If furnished with such a card the traveller would be able to record the form of the nose by simply noting the number of the type to which the nose of each person examined corresponds. The table of nasal indices in the living will prove useful for comparison with those of the bony parts.

The colour of the skin, eyes, and hair are dealt with in the following chapter in the same systematic manner as the previous characters treated of. Prof. Topinard concludes that there are only two types—the blond and the dark; that the other so-called types—yellow and red in particular, can only in a very minor degree serve to distinguish races, and that colour as a rule is an uncertain character, liable to alter in individuals, and difficult to determine and express. As a concession, however, to the general practice, he gives a table of classification of races by their colour under the three denominations—white, yellow, and black.

The cephalic index, unlike colour, is described as a character of prime importance in the classification of races, since it indicates the general form of that portion of the skull which contains the brain. Before the cephalic index can have the same value in all cases, it is absolutely necessary that there should be complete uniformity in the manner of measuring the length and breadth of the cranium, the two measurements from which it is deduced. Unfortunately this has not hitherto been the case. French anthropologists have uniformly measured the cranial length as that between the most prominent points of the glabella in front and the occipital behind in the mesial line, and the breadth between the most widely distant points on the same plane of the parietal or squamosal bones at right angles to the length. This we contend is the only satisfactory method of measuring these diameters. In England the anterior point of length has been taken until recently from the ophryon, while in Germany the length is measured from the glabella to a point on a line perpendicular to the most posterior part of the occiput at right angles to a plane adopted by the Frankfort agreement as the horizontal of the skull. The breadth likewise has been differently measured on the parietal bones or on the squamosals. Fortunately the methods of measuring these diameters is uniform now in France, England, and most other countries, except Germany. Skulls are classified according to their cephalic indices into three groups—dolichocephalic, mesaticephalic, and brachycephalic; but the limits assigned to each group by different anthropologists vary very considerably, as the tables in Prof. Topinard's work will show. The limits assigned by the author to each group are such as to commend his classification generally. He subdivides the dolichocephalic and brachycephalic groups—the former into dolichocephalic and sub-dolichocephalic, and the latter into sub-brachycephalic and supra-brachycephalic, and gives these subdivisions and the mesaticephalic group each a limit of five units. Thus we have practically five groups—viz. dolichocephalic, where the index is between 65 and 69 inclusive; sub-dolichocephalic, 70-74 inclusive; mesaticephalic, 75-79 inclusive; sub-brachycephalic, 80-84 inclusive; and supra-brachycephalic, 85-89 inclusive. Skulls with indices below or above the extreme limits of these groups are termed ultra-dolichocephalic and ultra-brachycephalic respectively. This classification and the limits of each class agree with the ideas on the subject most generally entertained, and we would earnestly urge their acceptance. In one small point the nomenclature might be improved by the insertion of the word "sus," or in English supra, to distinguish the higher group of the dolichocephalic class (if its omission is not an overlook in the correction of the proof sheets of the work) so as to make the nomenclature of this subdivision correspond to that of the higher division of the brachycephalic class—"sus-brachycephalic." The tables of cephalic indices of skulls and of the heads of various races will prove extremely useful for reference.

Chapters XIII. and XIV. are devoted to stature. The development of the skeleton and its variations in height are first considered; then, secondly, the stature of the inhabitants of different countries. These chapters contain much information collected together from many sources.

The two following chapters treat of the weight and size of the brain at different ages, and in different persons and races, its relation to the weight and stature of the body, and other questions of much interest regarding it, which will well repay perusal by those interested in neurology as well as anthropologists.

The next chapter (XVII.), on the cubage of the cranial cavity, will be read with much interest, being a subject to which Prof. Topinard has given special attention. It reveals the great diversity of opinion which still exists regarding the best method of measuring the capacity of the encephalon. A system of cubage easy of application which would yield constant results in the hands of different operators, and at the same time indicate the actual size of the encephalon would probably be readily accepted by most anthropologists. Broca's system, which is perhaps the one most generally used, gives constant results, but is somewhat complicated and does not indicate the absolute capacity. Even with its faults Prof. Topinard considers it is the best method we have at present, he however contemplates some modifications of it which will simplify it and make it more satisfactory. This being the case it is needless to criticise the chapter further at present, but pass on to the next subject—viz. the skull itself, its measurements, and its characters—a most important part of the work, occupying ten chapters. In the limited space at our disposal it is impossible to enter into an examination of this part of the work adequate to its importance. When it is studied in conjunction with Broca's "Instructions Craniologiques," the results of more extended researches on a larger amount of material and more matured views are observable. Many measurements recommended by Broca in his work published in 1876 were abandoned by him before his death or delegated to a place of secondary importance. If any exception can be taken to this part of Prof. Topinard's work it is that it is too much an exposition of Broca's views to the exclusion of those of the author. Broca's methods are strictly adhered to in some instances where more independent consideration with knowledge acquired since his death might have resulted in a modification of the opinions expressed regarding them.

After discussing the general development of the skull and the relations between the configuration of the exterior of the cranium and of the brain, the measurements of the skull are considered. The skull is divided into a cranial and a facial portion, and the measurements of each are detailed and their relative importance pointed out. The measurements of the cranial portion recommended and the method of making them are those usually adopted; those of the facial portion, however, will give rise to some discussion. The ophryon of Broca is shown to be somewhat unsatisfactory in its determination; Prof. Topinard with much pains shows that a better point is the supercilliary point, which corresponds to the most anterior part of the brain, and is situated in the mesial line immediately above the glabella on the level of a line drawn horizontally above the supercilliary ridges. It seems to us absurd to give a second name to a point so closely corresponding to the ophryon, and we would consequently recommend that the definition of the "point intersourcilier" should be considered only as an amendment of Broca's definition of the ophryon. Natural or pathological and artificial deformities of the cranium and their effect on the brain are very fully and ably considered and illustrated by woodcuts. The vexed question of the proper plane of orientation of the skull receives due consideration, and the condylo-alveolar plane, which was determined by Broca after much research, is recommended as the best and simplest. Of all the positions proposed we also consider this the best, and hope to see it universally adopted. From the skull in this position the prognathism of the several parts of the face is easily determined by means of a vertical equerry and a small triangular one. Prof. Topinard finds that the prognathism which is most important in distinguishing race characters is the alveolo-subspinal, and he figures five different typical modifications of the form of the face in this region. In his remarks on Prof. Flower's method of indicating prognathism we think Prof. Topinard has misunderstood the object of selecting the basio-nasial line as the standard of comparison. This line is specially chosen as being as nearly as possible the primary line of development of the skull, and because it is more constant than perhaps any other measurement of the skull. By means of the indices measurements from the basion to the alveolar point, or to the sub-nasal spine, with the basio-nasial radius, the relative prominence of the various parts of the face can be easily expressed, and compared in different races. Though Prof. Topinard's method is perhaps the more strictly correct one, that of Prof. Flower has the advantage in being the more practical, from its being simpler.

We may here remark regarding certain measurements recommended by Prof. Topinard between the occipital point and various points on the face, with the object of indicating its profile outline, that we consider it would be preferable if the basion was selected as the starting point for them, instead of the occipital point, on account of the former being much more fixed than the latter. The relative proportion which these radii bear to one another according as the occipital point is situated high up or low down on the occipital bone is very great; indeed so much so as to render their indices almost valueless for purposes of comparison. This fact has probably been overlooked by Prof. Topinard in his desire to obtain a method of measuring the skull, which would be applicable also to the head of the living person.

In treating of the facial index, Prof. Topinard adheres to Broca's method of measuring the length of the face from the ophryon. This point we consider very unsatisfactory, as two observers will seldom place it at exactly the same spot. The facial height is best measured from the nasion, and we prefer the facial index of Kollmann to that of Broca. The lines of contour of the face are valuable in demonstrating the relative proportions of the upper and lower parts of the face to the maximum or bizygomatic width, and supplement the facial indices.

The number of measurements of the mandible have been much reduced by Prof. Topinard, and it is studied more in connection with the skull, as it should be, than as a mere isolated bone.

Chapter XXVII. contains a useful *résumé* of the various systems of measurements of the skull employed in Germany and England, a table of the measurements considered by the author to be of prime importance, and a more extended list to be used in making more minute researches. The method of orientation of the skull and of making measurements in relation thereto, advocated by the Frankfort agreement, is very justly condemned, but in an unoffensive and truly scientific spirit.

The last chapters of the work treat of the characters of the trunk and extremities, and contain valuable tables of the proportions of these parts of the body in different races. Throughout the work the characters in the living subject are carefully considered side by side with those of the skeleton, which is of great practical value not only to the anthropologist alone but to artists and others wishing to make themselves acquainted with the subject of human morphology.

The work concludes with a carefully drawn up table of directions and measurements of the body for the use of travellers, which will doubtless prove very valuable, and we hope will be the means of bringing us more exact information regarding the physical characters of many races yet imperfectly described.

The work is one in every respect worthy of the author, and cannot fail of being highly appreciated by anthropologists everywhere. We hope the time may not be far distant when the other volumes promised will be in our hands.

J. G. GARSON

OUR BOOK SHELF

Our Insect Enemies. By Theodore Wood. 220 pp. small 8vo. (London: Society for Promoting Christian Knowledge, 1885.)

We have read the book through without discovering anything (save in some questions that may be regarded as essentially controversial) to find fault with. The illustrations are not numerous, but to the point, and, although somewhat coarse, are better selected than is sometimes the case in books of this nature. There are fourteen chapters in all, of which four are not inappropriately devoted to Aphides. The important subject indicated by the title is treated calmly, and apparently with a view to discourage the undoubtedly ill-effects produced by panic-mongers in economic entomology. The first (or "introductory") chapter is well considered and well reasoned.

Some Account of the "Palan Byoo," or "Teindoung Bo," (Paraponyx oryzalis), a Lepidopterous Insect-pest of the Rice-Plant in Burma. By J. Wood-Mason, Officiating Superintendent, Calcutta Museum. (Calcutta, 1885.)

A pamphlet of 12 pp., with a plate, concerning a lepidopterous larva that damages, but does not, as a rule, appear to kill the rice-plant. It is more useful as a contribution to pure biology than to economic entomology. It describes one of the few Lepidopterous larvæ that breathe mainly by gills (or branchiæ), and from this cause is considered an ally of our common little aquatic moth known as *Paraponyx stratiotalis.* The vernacular names by which the insect is known are not such as to be readily remembered by "foreigners;" yet it might have been better had the author not applied a scientific name based solely on larvæ and habits. All babies are supposed to be very much alike, save to the fond parents of each in particular.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Krakatão

Although I have not yet had the good fortune of reading Dr. Verbeek's "Krakatão," yet in the review published in Nature of October 22 (p. 601) there are one or two points I would like to draw attention to. In speaking of the earthquake of September, 1880, we are told that it may have facilitated the entrance of water by the Sunda fissure. If this were so, it certainly seems a strange thing that no less than three years should be necessary to heat the water before the explosion took place. I think that at present few geologists believe in water gaining access to the magma by fissures while we neglect percolation through porous rocks. It seems to me that the above earthquake was the result of rupture and extension of the magma-filled fissure towards the surface, in consequence of which the final outburst was put off for a short time by increasing the space for, and so lowering the tension of, the magma-filled fissure. By a careful study of the products of many volcanoes I have shown how the magma gradually dissolves or takes up within it water from the surrounding rocks, and as this is a slow process, the longer a volcano remains inactive, other things being equal, the more violent will be the subsequent eruption and the more vitreous will be the pumice owing to the rapid cooling of the magma froth in consequence of the large absorption of heat in converting the dissolved water into the gaseous state of steam, in the same way that the temperature of seltzer water falls on allowing the gas to escape on removal of the cork. The above earthquake has its parallels in A.D. 63 at Vesuvius, those of 1536 and 1537 at Monte Nuovo, and in the late Ischian shocks.

The thickness of ejected materials is certainly gigantic, for the maximum thickness of the Plinian eruption at Vesuvius was under 10 metres, or just one-sixth that of Kratakão.

There is reference made to round concretions called "Krakatão marbles" that are met with amongst the ejectamenta, as being things so far unobserved. Of course, it is not possible to judge clearly from the description, but I have little doubt that they may be similar to those met with in the marl-like tufa of Ischia and others, commonly found amongst the ejectamenta of Monte Nuovo, which at the latter locality are fossiliferous. They are simply concretions in a marine resorted tufa.

The cooling of the atmosphere, referred to, at Batavia and elsewhere at a moderate distance around the volcano, might be explained by the vortex inrush of air towards the vapour column. Observations of wind direction would be interesting as settling this point.

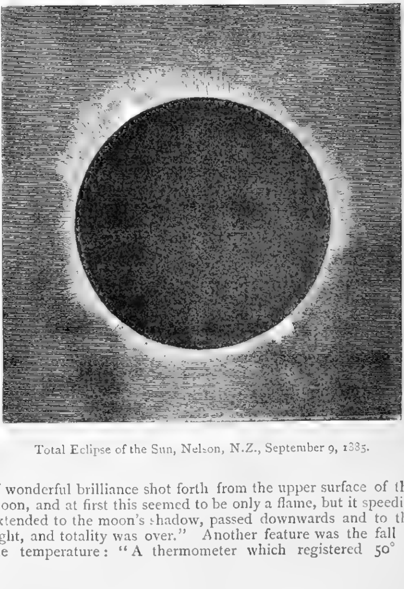
Another question of interest that was raised is the cause of non-correspondence of one part of the earth with another in seismic or volcanic activity. If we suppose a volcano to be supplied with magma by ramifications from large extensions of fluid rock within our globe, the gradual absorption of water by one of these ramifications, and the consequent increase in its tension may be quite independent of another ramification not far off, yet perhaps more or less favourably placed in relation to porous strata and superincumbent pressure and the necessary results.

I have drawn attention to these few points not with any intention to undervalue the report, which has all the characters of being one of the most important additions to the vulcanological literature of the nineteenth century, but simply to prevent certain unsound theories from becoming current.

Naples, October 26 H. J. Johnston-Lavis

The Recent Total Eclipse of the Sun

It may be interesting to your readers to supplement the description given in Nature, vol. xxxii. p. 631, with the following notes which I have just received from a friend who observed the eclipse at Nelson, N.Z.: "As the period of totality passed away, a bright point of light as from a diamond



Total Eclipse of the Sun, Nelson, N.Z., September 9, 1885.

of wonderful brilliance shot forth from the upper surface of the moon, and at first this seemed to be only a flame, but it speedily extended to the moon's shadow, passed downwards and to the right, and totality was over." Another feature was the fall in the temperature: "A thermometer which registered 50° at seven o'clock, stood at 30° immediately after totality; the keen breeze which was blowing before the sun was shadowed died completely away at the time of totality." I inclose a photograph which clearly shows the protuberances noticed by all the observers. KILLINGWORTH HEDGES

Westminster, October 30

An Earthquake Invention

THE object I had in view in my former communication to NATURE (vol. xxxii. p. 213) on this subject, has been attained, as the following quotations from Prof. Milne's letter in NATURE (p. 573) show: "I have no desire to claim the authorship of the aseismatic joint;" and again, "I am as yet in the dark as to who was the first inventor of the aseismatic joint."

Well, I can enlighten him, and I claim the invention for Mr. David Stevenson, whose paper describing it was read before the Royal Scottish Society of Arts in 1868, and published in their *Transactions;* whose firm designed, superintended the construction of, tested and sent out to Japan seven lighthouse apparatus, carried on tables 8 feet in diameter, fitted with this contrivance. Further Messrs. Stevenson designed two lighthouse *buildings,* iron towers 29 feet in diameter at the base and 46 feet in height, with an aseismatic joint *at their base,* which were constructed and *erected* in the work-yard of the contractors in Edinburgh, and finally, in 1869, shipped to Japan, but unfortunately they never reached their destination, as the vessel went down on the voyage out.

There are three points in Prof. Milne's letter on which I wish to make a few remarks. The first is to give the explanation Prof. Milne asks as to the part the late Mr. Mallet took in the invention of the aseismatic joint which I may observe Mr. Mallet never claimed for himself. Mr. Stevenson consulted with Mr. Mallet as to what was the exact *mécanique* of an earthquake shock, and how he thought it would affect the delicate apparatus usually placed in a lighthouse. This information Mr. Mallet furnished, but so far from suggesting a ball and plate joint, he expressed a fear that the superstructure, if placed on balls as proposed by Mr. Stevenson, would be thrown down, and in a letter dated March 14, 1868, acknowledging a copy of the *Scotsman* newspaper, containing a notice of Mr. Stevenson's paper, he says that if the balls and plates proposed are confined to the apparatus in the light-room, he "would augur much more favourably of the result being satisfactory," but that his "own notion for Japan or other shaky places would be to make all the towers rather of timber or of boiler plate work." This, I think, should put Prof. Milne's mind at rest on this point.

The second point is with reference to ball and plate seismographs. I never described a seismograph, but my brother did, in 1883, in NATURE, vol. xxviii. p. 117, though, so far from claiming the *idea* as original, he says: "The idea of the instrument I propose was suggested to me by the aseismatic arrangement designed by my father, Mr. David Stevenson, for averting damage to buildings and lighthouse apparatus in countries subject to earthquakes."

I entirely agree with Prof. Milne that the joint employed in ball and plate seismographs, lamp tables in Japanese lighthouses, model houses, and the Professor's own dwelling-house, all "involve the same principles, and they only differ in their dimensions," and my point is that Mr. David Stevenson was not only the original inventor of this contrivance, but, what is of far more importance, suggested and carried into practice *the* only known method of mitigating the effects of earthquake-shocks on buildings, and the astatic house of which Prof. Milne reported such good results to the British Association of 1885, which is described in NATURE, vol. xxxii. p. 527, as being "rested at each of its piers upon a handful of cast-iron shot each a quarter of an inch in diameter" placed "between flat iron plates," is obviously merely a modification of the same principle.

The third point is as to the success of the aseismatic joint. It does seem a little curious that Prof. Milne, in the *Transactions,* British Association of 1884, when he appeared to me and to others to claim the invention for himself, thought it perfection, though now he appears to have changed his mind. I do not think, however, it affects the question at issue, whether the aseismatic joint is a success or not; but that it is a success will be seen from Prof. Milne's own reports in the *Transactions* of the British Association, and from the following information which was supplied by Mr. Simpkin in 1884, who had just returned from Japan, where he was engaged in the lighthouse service. At Isuragisaki and Kashmasaki lighthouses the aseismatic tables were firmly strutted with timber to prevent any motion, as inconvenience was felt from the oscillations of the table when winding up the machine, the steadying screws sent out with the apparatus for the purpose of temporarily doing so having for some reason not been put in at these stations. These two are the only lighthouses at which any damage has been done by earthquake, while those stations at which the tables are in operation have never suffered at all, although they have been repeatedly subjected to shocks: but for full particulars as to this see NATURE, vol. xxx. p. 193, and vol. xxxii. p. 316.

Prof. Milne excuses himself on the ground that he was 10,000 miles away from a library and never saw Mr. Stevenson's paper, but surely NATURE finds its way out to Japan, and this subject has been referred to in your columns frequently; it was also discussed in 1876 before the Institution of Civil Engineers, and an account of it was published in their *Transactions;* but, after all, the apparatus was actually at work in Japan where he was living. D. A. STEVENSON

The Mithun

I WAS glad to see in NATURE of July 16 (p. 243) that Mr. W. F. Blanford had drawn attention to the extraordinary mistake made by Dr. Kuhn in considering the gayal and gaur specifically identical, and their differences as due to domestication. If this latter were true we should see endless intermediate forms instead of two invariably distinct. To those who know them in their habitat the confusion must seem extraordinary, even though both are here called "Mithun." The gayal (*B. frontalis,* v. *gavæus*) is known (domestic only) all through these hills, and not in the plains; is pied black and white, with pink muzzle, white legs, and the tips of the horns point *outwards.* The gaur (*B. gaurus,* v. *cavifrons*) is only known wild, in the hills and also plains, never pied, has white legs, and the tips of adult horns invariably point *inwards.* The gayal domestic, and never known wild; the gaur wild, and never known domestic; and they do not cross. I have known both here now many years, and had good opportunities of observing and contrasting them. I have had a fine bull gaur feeding along beside me at twenty yards in short grass for over quarter of an hour, as I sat motionless in my Rob Roy canoe, an enormous Dontal (tusker) elephant at the same distance off on the opposite bank; each occasionally left off to sniff me, but resumed again, taking me, in brown-grey costume and grey-coloured canoe, for a snag in midstream (which stream was deep and stagnant). It is not always easy or possible to point out to such a man as Dr. Kuhn that the study of the "dry bones" of an animal is really but half the battle in comparing it with its allies. The study of specific distinctions should include the whole animal, alive as well as dead.

But the clearest proof that these two distinct forms are not due to domestication is that, instead of endless intermediate forms, we find absolutely none. S. E. PEAL

Sibsagar, Asam, September 26

On the Behaviour of Stretched India-rubber when Heated

I SHOULD like to make the following remarks with reference to the letter of Mr. H. G. Madan which appeared in the last number of NATURE:—

(*a*) Though the fact that india-rubber becomes *hot* when *stretched* might be, and no doubt is to be, *partly* attributed to molecular friction, we cannot thus account for the *cooling* which resulted from *contraction* in the experiments of Joule and Sir William Thomson.

(*b*) Text-books as a rule are not, I am afraid, sufficiently explicit as to whether the stretched india-rubber is contracted in *volume* when heated, or only in *length.* Thermodynamic theory does not require, in order that longitudinal pull should produce rise of temperature, that the *volume* should be diminished when the temperature is raised, and the results of Joule's experiments are in reasonable accord with theory.

(*c*) The real state of things seems to be that the effect of heating a stretched piece of india-rubber is to *lengthen* it if the tension is *small,* and to *shorten* it if the tension is large (Hr. Schmulewitsch, *Vierteljahrschrift der Naturforsch. Gesellschaft, Zürich,* xi. 202); thus, for a certain tension there will be neither elongation nor contraction, and my own experiments on the effects of stress on the physical properties of matter lead me to infer that the critical tension will be lower the higher the temperature. HERBERT TOMLINSON

King's College, Strand, October 31

The Resting Position of Oysters

As your correspondent, Mr. J. T. Cunningham, expresses a doubt as to the evidence on which the current belief of conchologists is founded that oysters rest on the convex valve, I beg to inclose a cluster of three, brought to me among others from Torbay this morning. They are all attached by their convex valves, and confirm the descriptions of Messrs. Woodward, Jeffreys, and Huxley.

Mr. Cunningham's Sertularia and Thuiaria go to prove that he has seen oysters from the Firth of Forth that rested on their flat valves. This is easily accounted for. Solitary, unattached oysters, resting on the sea-bottom, would easily, from their peculiar form, be turned over by wave-currents (if exposed to them); or they might fall on their flat valves when thrown overboard by dredges as too young for market. In either case, once overturned, they would be powerless to regain their natural position.

With regard to the Pectens, Mr. Cunningham does not specify the species found covered, as to the convex valves, with Balanus, &c. In two such common sorts as *P. maximus* and *P. opercularis*, we find in the one the under-valve more convex, in the other the upper valve. In each case the mollusk rests on the same valve. ARTHUR R. HUNT

Torquay, October 27

Salmo salar and S. ferox in Tasmania

In your issue of October 29 is a communication from Mr. Saville Kent, in which he "concludes that no true salmon has yet been established in the lakes and rivers of Tasmania. The fish of large size which abound in the great lakes and other large sheets of water are really essentially the same as the great lake trout, *Salmo ferox*, of Great Britain."

Respecting the salmon, although very possibly Mr. Kent has not yet seen a true one in Tasmania, such does not absolutely prove their absence. In the *Field* of last May I drew attention to an undoubted salmon smolt, 9 inches long, which was sent home from Tasmania by Mr. Robins, on January 3, 1880, and is now in the national collection.

As regards the great lake trout, I observed in the *Proceedings* of the Zoological Society, January 15, 1884, that the original stock of British fresh-water trout from which ova were procured to send to Tasmania, were solely obtained in Hampshire and Buckinghamshire, localities where the great lake trout is not found, *unless it is merely a variety of the brook trout.*

The late Mr. W. Arthur, whose recent death at Dunedin will prove an irreparable loss respecting these investigations, sent me two specimens in ice in July 1883. One was a male, 32½ inches long, the other a female, one inch less. I remarked that "these two beautiful specimens of trout are so exceedingly similar to so-called lake trout, that any ichthyologist who believed in the numerous species of this fish, and was unaware from whence they came, would undoubtedly term them *Salmo ferox*."

Whether Mr. Saville Kent in the note in question considers the great lake trout, *S. ferox*, a distinct species from the brook trout, *S. fario*, seems left to the reader to surmise. Should he be correct in his identification (as I believe him to be), then the great lake trout has been raised from the eggs of the small brook trout, showing it to be merely a variety which, under favourable conditions, will attain to a large size. FRANCIS DAY

Cheltenham, October 30

A Right-footed Parrot

If my memory does not deceive me, Mr. Romanes asked some months ago for an account of any peculiarities shown by parrots, in which case you may be able to find a corner for the following incident:—

Last Sunday I gave our parrot—an ordinary grey bird—the hardest walnut I could find, as when busy cracking the shell she is less noisy. After struggling for a long time in vain, at first on the perch and then on the bottom of the cage, holding the walnut as usual with the right foot, she changed feet, whether because the right foot was tired or not I cannot say; but now utterly failed to make the walnut reach her beak. Time after time the walnut was raised above the bird's head, rather over the neck. At the same time she was unable to stand steady, but fell over and rested on her right wing. After about a dozen fruitless attempts, and by the time every one in the room was shaking with laughter, she flung the walnut down with a shriek and returned to her perch. C. V. BOYS

The New British Myzostoma

SINCE recording the discovery of an encysting *Myzostoma* on the Comatulæ of Milford Haven (NATURE, August 27, p. 391) I have examined a large number of other examples of *Antedon rosacea* from different British localities; and I have found *Myzostoma*-cysts or other modifications of the pinnule-joints on individuals from Torquay, Cumbræ, Arran, and Oban, while in one or two cases the arm-joints are also affected. Prof. A. C. Haddon has kindly sent me some Comatulæ which he dredged last summer in Berehaven, County Cork, and in Dalkey Sound, County Dublin, and I have found slightly malformed pinnules in one individual from each locality, though there are no traces of definite cysts. It is clear, however, from what has been said above, that this encysting *Myzostoma* has a tolerably wide distribution in the British area; and I shall be very glad to hear of its discovery on Comatulæ from other localities than those which I have mentioned.

The cysts are fairly conspicuous on the Cumbræ specimens (dredged by Mr. Sladen), though nothing like the size of those which occur on the Crinoids of more tropical seas; and I suppose that this is the cause of their having so long escaped the notice of the many naturalists who have dredged at this locality. Now, however, that attention has been directed to them, it is quite possible that they may be discovered at Roscoff and at various localities in the Mediterranean, where *Antedon rosacea* is equally abundant. P. HERBERT CARPENTER

Eton College, October 31

Tertiary Rainbows

THE following extract from my journal may be of interest with regard to the subject of "Tertiary Rainbows":—

"May 5, 1885.—Extraordinary display of rainbows at 4.30 p.m. on Grand Trunk Railway between Kingston and Montreal. *Six* bows in all were seen. The primary was flanked on the inside by four bows quite near, and on the outside at some distance by a fifth."

The bows were all quite distinct, but of course of decreasing brightness in passing from the primary inward. They were noticed by several persons besides myself.

W. L. GOODWIN

Queen's University, Kingston, Ontario, October 15

"Furculum" or "Furcula"

DR. SCLATER in his letter to NATURE (vol. xxxii. p. 466) calls attention to a very interesting point in regard to the use of the word *furculum*, asking, as he does so, for its authority. Not only are the eminent anatomists—Balfour, Huxley, and Rolleston—mentioned by him, authorities for it, but the majority of anatomical writers, both of the Continent and Great Britain; they having also lent their influence, through custom, to the introduction of this word. In this country the same holds true, and the use of the term *furculum* for *furcula* receives the support of such high authority as Marsh ("Odontornithes," p. 58, Fig. 14*f.*) and many others.

Dr. Sclater further states that he has failed to find its use sanctioned by any dictionary. For the large dictionaries of the language this no doubt is true, but in quite a number of works upon anatomy that present us with a "glossary of terms," we find the word *furculum* given, and not *furcula*, as, for instance, see "Elements of Zoology," by M. Harbison, Head Master, Model School, Newtownards, and "Handbook of Vertebrate Dissection," Part II., by Martin and Moole. More than this, *furculum* is the only word given in certain scientific dictionaries, as Dunman's "Glossary of Scientific Terms," London, 1878, and published by D. Appleton and Co., New York, 1879.

I find myself also in the same category, deserving the censure of your correspondent, and agree with him entirely in the incorrect use of the word *furculum* for *furcula*, or still more properly

as he suggests, though perhaps less convenient term, *os furculatorium*.
R. W. SHUFELDT
Fort Wingate, New Mexico, October 8

Metric or English Measures?

WOULD any of your readers have the great kindness to give me their opinion on the following question?

In writing a school-book in which such branches of physics as dynamics and heat are to be treated in a very elementary but exact way, would it be best to use the metric system or the English system of weights and measures?

Personally, I am strongly inclined to take the former course; it seems to me that as soon as a boy's scientific education begins he should make acquaintance with the units of measurement now generally adopted by scientific men throughout the world.
E. R. P.

CHARLES ROBIN

ON the 6th of last month died in Josseron (Department l'Ain) Charles Robin, sixty-four years old. He was one of the few men in Europe who may be justly considered the founders of modern histology. Although some of his views, as, for instance, on the formation of cells out of a blastema, are now only of historical interest, there remain a considerable number of valuable facts which he has contributed to histology, anatomy, and zoology. A chair of General Anatomy was created for him in 1862 in the Paris Faculty of Medicine, and here he always collected round him a number of ardent students who, under his direction and imbued with his ideas, did excellent work in histology. He was, in fact, until a few years back (until Ranvier) the only exponent of and original worker in histology in France. There is hardly a chapter in this science to which he has not largely contributed. His chief works are "The Natural History of Vegetable Parasites in Man and Animals"; "On the Tissues and Secretions"; and his many articles in the "Dictionnaire Encyclopédique des Sciences Médicales."

THE LIVERPOOL INTERNATIONAL EXHIBITION

THE credit of the inception of the idea of the practicability of carrying on an International Exhibition at Liverpool appears to be due to Alderman David Radcliffe, the present Mayor of the City, who laid it before Lord Derby, who at once became the first guarantor of a fund which now exceeds 60,000*l*. The support this movement has now secured in England and on the Continent renders its success assured.

It is a matter of surprise that no International Exhibition has ever yet taken place in the North of England, when the fact is remembered, commented on by Lord Derby at the last annual banquet given to him by the Mayor of Liverpool, that the inhabitants of that City and the district lying within a radius of fifty miles of it are as numerous as those of the City of London, and the greater London, which lies within a radius of fifty miles of St. Paul's. The value of exhibitions it is difficult to over-estimate. Visitors however unintelligent must of necessity learn something of the processes and methods carried out by their countrymen in the arts and manufactures, while the exhibitors increase their technical grasp, and get their thoughts removed from stereotyped grooves by the inspection of products from countries where workmen obtain so much larger a share of technical education, based on practical science, than is accorded by the education department of this country.

Placed as is Britain, as it were between Europe and America, an Exhibition of Navigation and Travel would at all times appear to be singularly appropriate: but this has still greater significance at Liverpool, itself the second, if not the first, seaport of the world. This is rendered still more important from the evident care evinced by the projectors that the Exhibition should be on a scientific basis, and that it should be the means of spreading accurate scientific and technical knowledge in the construction and manipulation of all the appliances of locomotion, travel, and transport by sea and land, by rivers, by air, or through cultivated lands, or across the desert. In addition to this it is proposed, should, as is hoped, a surplus be realised at the end of the Exhibition, that it be devoted to the foundation of a school of technical education, to be called after the late Prince Leopold, whose last public appearance in Liverpool was marked by special advocacy of the claims of technical education.

Commerce and manufactures are also to be represented, including all substances used in the arts derived from animals, from vegetables, and from metallic and non-metallic minerals.

The Corporation of Liverpool has granted a site of 35 acres near the Edge Hill Station of the London and North-Western Railway; fountains, bands, and electric illuminated trees are to reproduce the features of South Kensington, and the scheme is not only supported by the cities of the north, but by Paris, Vienna, and Berlin, while Belgium, Sweden, and other countries, and the Isle of Man, are applying for courts. The Exhibition will be opened in May next year, and continue open for six months.
C. E. DE RANCE

DR. GOULD'S WORK IN THE ARGENTINE REPUBLIC

WE have from time to time during the last fifteen years recorded the progress made by Dr. Gould in his stupendous work on the southern stars. He has now returned to the United States, and we are glad to be able to give an account of the reception he met with on his return. Rarely has such a reception been better deserved, and carried out as it was it did credit to science all the world over, as well as to the country and the man most closely interested.

A letter signed by upwards of eighty of the most prominent men in Boston awaited Dr. Gould's arrival, asking him to fix a date "when it will be agreeable for you to meet us at a dinner, that we may welcome you home."

Pursuant to arrangement a reception and dinner took place at the Hotel Vendôme, Boston, on the evening of May 6, 1885. The Hon. Leverett Saltonstall presided, and, after the banquet, arose to introduce the guest of the evening. The president referred to Dr. Gould's early career and his hard work:—"We have thus met," he said, "that we may extend to Dr. Gould our most cordial welcome, to show him our high respect for his character and attainments, to express to him our deep sympathy for all the severe trials he has been called upon to encounter, and to prove to him in every possible way how proud we are of his high fame, world-wide, as one of the greatest astronomers of this or any former age. . . .

"When the opportunity presented itself for doing a far greater work than that, in my opinion, accomplished by any astronomer now living, and equalled in extent and importance by but few in any previous age, a work so vast in its design that its mere suggestion might well have staggered a much younger man, he already having passed what is considered the prime of life, courageously took the great step and exiled himself from home, conscious that it was a work which he could scarcely hope to live to complete. He buried himself in a country so far away and so little known that it might well have seemed another world, and with no hope of reward such as the world generally values for all the cause he loves with such devotion—the cause of science. He sailed with his family for Buenos Aires, and there for fifteen years he has been searching the heavens by night, and making his calculations by day, till he has finished a complete catalogue of the stars of the southern hemisphere. And in this great work, the greatest perhaps ever known, an exile from home, almost alone and unaided, feeling that on the continuance of his life and strength depended its accomplishment, he braved and endured all with a courage and devotion worthy of our highest admiration."

In reply to the toast of his health, Dr. Gould spoke as follows:—

MY DEAR FRIENDS,—Would that I knew how to give some fit expression to my deep sense of your kindness, and to my gratitude for this delightful manifestation of your approval and regard. No man could fail to be profoundly moved, or to indulge a pardonable pride, under such circumstances; and it is only natural that one, who is perhaps too sensitive to the opinions of those whom he loves and esteems, should find it difficult to control his emotions or to give full utterance to his thanks.

If the pursuance of my appointed task has entailed sacrifices, the chief among them has certainly been the long separation from the friends at home, whose companionship, encouragement and sympathy were always my greatest source of happiness, outside the narrow limits of domestic life. But there has been something more than mere separation; for, however cherished and abiding may be our memory in the hearts of the friends spared to us for that reunion to which we are always yearningly looking forward, there still remains the consciousness that we have ceased to form an element in their lives, and that all human associations become dulled by the lapse of time. Had I been able to foresee this welcome from those to whom I am most closely bound by ties of affection, sympathy and respect, the anticipation would have lightened many a weary hour, and given new strength when courage threatened to fail.

You, my dear classmates of forty years ago, like the other friends around us here, need not be reminded that public speaking was never comprised in the short list of my attainments. It will not surprise you that fifteen years' disuse of our native language should have given me no greater command of it, nor that an unremitting employment of telescopes and logarithm-tables, should have made it no easier to face a large assemblage, even though composed only of kind and indulgent friends. All that I can do is to offer to all of you my overflowing thanks, and to assure you that the long severance from friends and country, now at last ended, shall give greater earnestness to my resolve to atone in the future, as well as may be, for the past neglect of my duties to them and to this community, in which I will never abdicate my priceless birthright.

As you have implied in your too flattering words, that incentive has never been wanting during my expatriation, which came from the consciousness that whatever it might be within my power to accomplish well, would be credited in part to our native land. It is a source of pride to the Argentines that their political organisation was modelled upon that of the United States—that their precedents in constitutional law are based upon the decisions of North American courts, and that the word "America" vibrates in their ears with the same melody we know so well. If a conquest from the realm of the unknown be made by American effort, they rejoice in it, before considering which is the hemisphere whence the soldiery came. And the success of any laudable effort emanating from this western hemisphere is doubly prized by them when the two Americas have united for its accomplishment.

Science knows no narrow bounds of nationality; yet who would be so cruel or so unwise as to censure, or attempt to weaken, the intense stimulus which is given by the hope that what honour may attach to a good work will be reflected upon one's own country? Does not a part of the world's tribute to a Franklin, Fulton, Bache, Henry, Agassiz, or Peirce—to an Irving, Bryant, Prescott, Motley, or Longfellow (I name only such as have left us)—belong to their country? And is it not a wholesome incentive to the labourer that he should feel that a portion of his reward will be assigned to his country, or even in a wider sense, to his own continent, when this has started late in the race, handicapped by the shortness of its history and the restrictions of its past opportunities?

From this point of view it may not be unseemly if I comply with the request to relate briefly what has been attained at Cordoba in these fourteen and a half years, chiefly by North Americans, labouring in the service of the Argentine nation, which has never failed to afford them all needful support and encouragement.

The undertaking began, as you know, with the project of a private astronomical expedition, for which my friends in Boston and its vicinity had promised the pecuniary means. The selection of Cordoba, as an especially desirable place, was chiefly due to our lamented countryman, Gilliss, whose astronomical mission to Santiago de Chile had resulted in extensive and valuable observations of southern stars, and in the establishment of a national observatory, while it had enabled him to form a sound judgment as to the relative advantages of different points in South America for astronomical purposes, notwithstanding the total want of trustworthy meteorological data. This choice of place was confirmed by the counsel of the Argentine Minister to this country. That minister was Sarmiento, a man who needs no encomium here, for, during his brief residence in the United States, he gained an exceptional number of friends and admirers. He transmitted to his Government, then under the presidency of Gen. Mitre, my application for certain privileges and assurances, all of which were at once cordially conceded; but his interest in the plan became furthermore so great that when, soon afterwards, he was himself elected President, he obtained the assent of the Argentine Congress to the establishment of a national observatory, and wrote asking me to change my plans accordingly. The official invitation was sent in due time by the Minister of Public Instruction, Dr. Avellaneda. The Government assumed the expense of the instruments and equipments already bespoken, and authorised the engagement of the requisite assistants.

In 1874 Dr. Avellaneda succeeded Sarmiento in the presidency, and in 1880 he was himself succeeded by Gen. Roca. Thus, four successive administrations have encouraged and sustained the undertaking; and, notwithstanding the high political excitement which often prevails, and might easily have disinclined the members of any one party to give cordial aid to institutions established or fostered by its opponents, there has never been wanting a spirit of decided friendliness to the Observatory and to the scientific interests which have been developed under its auspices. No president of the nation, and no minister of the department under which the Observatory is placed, has failed to give strong practical evidence of his good will; there has been none of them to whom I do not owe a debt of gratitude; I have never made an official request which has not been granted, and almost always in such a way as to enhance the favour. And, just as the official founders of the Observatory met us with a cordial welcome on our arrival, so the Government of to-day has overwhelmed me with kindness and tokens of regard on my departure. On the very last evening before embarking—when it was my privilege to receive the farewells of a crowded assemblage in the halls of the Argentine Geographical Institute, and to hear words of sympathy and commendation from the lips of Gen. Sarmiento, my earliest Argentine friend, speaking in behalf of that Society—I replied, in the few words which alone were possible at the time, but with all sincerity and truthfulness, as follows:—

"It was you, sir, who provided the opportunity for which I was yearning; it was the Argentine Republic which made it easy for me to avail myself of it; it has been the National Government which, in its various phases, and under so many different administrations, always provided all needful means and resources; it is the Argentine people which has accompanied me in my tasks, giving support by their sympathy and incentive by their kindness."

The original purpose of the expedition was to make a thorough survey of the southern heavens by means of observations in zones between the parallel of 30° and the polar circle; but the plan grew under the influence of circumstances, until the scrutiny comprised the whole region from the tropic to within 10° of the pole—somewhat more than 57° in width, instead of 37°. Although it was no part of the original design to perform all the numerical computations, and still less to bring the results into the form of a finished catalogue, it has been my exceptional privilege, unique in astronomical history so far as I am aware, to enjoy the means and opportunity for personally supervising all that vast labour, and to see the results published in their definite, permanent form. Of course this has required time. The three years which I had purposed devoting to the less complete work have been drawn out to nearly fifteen ; and you will comprehend what that implies for one who loves the friends of his youth, his kindred, and his country. Yet even here there has been consolation. For, while the work has demanded all that period, it did not absorb the whole time, and opportunity was left for other studies. Among the astronomical ones it has been possible to examine all the stars as bright as the seventh magnitude, up to 10° of north declination, for careful estimates of their respective brilliancy, and to reform the arrangement and boundaries of the southern constellations. Also to carry out the observations and computations for another stellar catalogue, more precise than that of the zones, and extending over the whole southern hemisphere. The total number of stars in this catalogue is less than in the other; but that of the observations is greater, since each star has been observed several times, as well as with greater precision. This catalogue, too, is at last finished and in the hands of the printer, and thus it is that I am once more at home with you, my cherished friends.

I am hopeful that the data now collected may throw some additional light upon the great problem of the distribution of the stars in space. Yet, even should these prove insufficient, there is reason to believe that the new labours, already begun by my successor, Dr. Thome, who has been connected with the observatory from the very first, will provide whatever additional information may be needful for the purpose. Among the other researches which have gone forward, while the preparation of the zone-catalogue dragged its slow length along, has been a study of the meteorology of the country. The absolute lack of information on the subject had forced itself unpleasantly upon my notice when endeavouring to select the most suitable place for the observatory ; and, as it would have been disgraceful for any scientific inquirer to reside in the country without trying to supply the want in some degree, I succeeded in enlisting the aid of various educated men and women in different parts of the country and adjacent ones. The Government and Congress acceded to my recommendation that a modest sum should be annually appropriated for the purchase of barometers, thermometers, rain-gauges, &c., to be lent to volunteer observers, and for arranging, computing, and publishing the results. In this way was organised, in 1872, the Argentine Meteorological Office, which has established no less than fifty-two stations, scattered from the Andes to the Atlantic, and from Bolivia to Tierra del Fuego. At the end of the year 1884 there were already twenty-three points at which the observations had been continuously made, three times a day, for at least four years, and sixteen others at which they had already been continued for more than two years. These have provided the necessary data for constructing the isothermal lines, with tolerable precision, for all of South America from the torrid zone to Cape Horn. Some little has also been accomplished in determining local constants of terrestrial magnetism ; and our determinations of geographical position have nearly kept pace with the extension of the telegraph wires. The beats of the Cordoba clock have been heard and automatically recorded amid the plash both of Atlantic and Pacific waves. And the series of longitude determinations made by the United States naval expeditions, between Buenos Aires and Europe on the one side, under Capt. Green, and between the United States and Valparaiso under Capt. Davis on the other, give, when combined with the two South American measurements, values for the longitude of Cordoba, which differ only by one-sixth of a second—this being the total amount of the aggregate errors of the several determinations in a series which, passing through Brazil, the Cape Verde Islands, Madeira, Portugal, England, Ireland, Newfoundland, the United States, Central America, and down the coasts of Ecuador, Peru, and Chile, completes the full circuit at Cordoba again.

But I will not descant upon collateral matters, nor convert this gathering of friends into an astronomical lecture-room. There are but two points more that I wish to mention.

One is, that I cherish a hope that our sojourn at Cordoba may hereafter be considered as marking an epoch in a new method of astronomical observation, namely, the photographic. The inception and introduction of this method belongs to our countryman, Mr. Rutherfurd ; and it was only through his friendly aid in several ways that I was enabled to give it a larger scope, in spite of many obstacles. Now I can report that every important cluster of stars in the southern hemisphere has been repeatedly photographed at Cordoba with a precision of definition in the stellar images which permits accurate microscopic measurement ; that these measurements are at present actively going on, and that the Argentine Government has undertaken to provide the means for their continuance under my supervision. It may be that I over-estimate the importance of this new method ; but I confess that my expectations are very high. Another year ought to show us whether they are exaggerated or not.

The other point is, that a very large share of the merit which you so liberally attribute to me belongs to the faithful staff of fellow workers, with whose assistance I have been singularly favoured. Their unselfish devotion to the great undertakings in which they took part, their loyalty, trustworthiness and ability, have, in the great majority of cases, been beyond all praise. Happily, their faithful and inestimable services to science are placed on durable record ; and yet unborn astronomers will know, at least in part, how great have been their deserts. The senior of them, Dr. John M. Thome, whose services began in 1870, before we started southward, is now director of the Observatory, where he has begun a new and important work, which will do honour to him and to the institution. Another, Mr. Walter G. Davis, who has laboured most earnestly and efficiently for eight and a half years, is now director of the Meteorological Office, which is assuming large proportions, and under which he is now organising at Cordoba a meteorological station of the highest class. One noble young man, Mr. Stevens, was summoned, without an instant's warning, to a higher reward than earth could give, leaving no memories behind him other than of affection, admiration, and respect. It was a sore loss for us, and for the bereaved parents in New Hampshire, to whom he was their only earthly stay and staff. Had he lived, his friends and country would have had abundant cause for pride in him. As it is, the number of those who love and honour his memory may perhaps be smaller, but their pride and admiration are no less, than had they seen the full harvest instead of the rich promise only. Mr. Bachmann, a native of Austria, who laboured with us for more than ten years, is now at the head of the Argentine Naval Academy in Buenos Aires, with more than three hundred pupils and an elegant little observatory, where he finds repose from administrative cares, in astronomical work analogous to that to which he gave his energies at Cordoba. He has already undertaken some longitude-determinations and arranged a time-ball, which is probably by this time giving daily signals by which the shipping in the outer roads, twelve miles away, may correct and rate their chronometers.

I have spoken longer than I intended, but will make no apologies, for I know your friendly indulgence. It only remains to say, for these Argentine scientific institutions, that I believe their success is now assured. They will enter upon new and enlarged fields of usefulness, as indeed they ought, for the world moves. And for myself, that the remembrance of this occasion and of your goodness will be a source of pride to me through life, and to my children afterwards.

Hardly had the sound of Dr. Gould's voice died away when he was the recipient of a splendid ovation, the guests of the evening seeming to vie with each other in a generous rivalry as to which should outdo the other in rendering honour to the distinguished guest of the evening.

The chairman, in introducing Dr. Oliver Wendell Holmes, pleasantly referred to him as not a small star, but one of the first magnitude. Dr. Holmes received just such a welcome as he is entitled to, and which is always accorded him, and in response thereto read the following poem, which was received with round after round of applause :—

A Welcome to Dr. Benjamin Apthorp Gould

Once more Orion and the sister Seven
 Look on thee from the skies that hailed thy birth—
How shall we welcome thee, whose home was Heaven,
 From thy celestial wanderings back to earth?

Science has kept her midnight taper burning
 To greet thy coming with its vestal flame :
Friendship has murmured, "When art thou returning?'
 "Not yet! Not yet!" the answering message came.

Thine was unstinted zeal, unchilled devotion,
While the blue realm had kingdoms to explore—
Patience, like his who ploughed the unfurrowed ocean,
Till o'er its margin loomed San Salvador.

Through the long nights I see thee ever waking,
Thy footstool earth, thy roof the hemisphere,
While with thy griefs our weaker hearts are aching,
Firm as thine equatorial's rock-based pier.

The souls that voyaged the azure depths before thee
Watch with thy tireless vigils, all unseen—
Tycho and Kepler bend benignant o'er thee,
And with his toy-like tube the Florentine—

He at whose word the orb that bore him shivered
To find her central sovereignty disowned,
While the wan lips of priest and pontiff quivered,
Their jargon stilled, their Baal disenthroned.

Flamsteed and Newton look with brows unclouded,
Their strife forgotten with its faded scars—
(Titans, who found the world of space too crowded
To walk in peace among its myriad stars).

All cluster round thee—seers of earliest ages,
Persians, Ionians, Mizraim's learned kings,
From the dim days of Shinar's hoary sages
To his who weighed the planet's fluid rings.

And we, for whom the northern heavens are lighted,
For whom the storm has passed, the sun has smiled,
Our clouds all scattered, all our stars united,
We claim thee, clasp thee, like a long-lost child.

Fresh from the spangled vault's o'erarching splendour,
Thy lonely pillar, thy revolving dome,
In heartfelt accents, proud, rejoicing, tender,
We bid thee welcome to thine earthly home.

The Rev. James Freeman Clarke in saying a word in honour of "our friend, the eminent astronomer, who is our guest to-night," remarked that—

"We are on the verge of still greater discoveries than any yet made, and our own country is prepared to do its full part in the work. When the Russian Government wishes for a better telescope than any now in Europe, it sends to Cambridgeport to get it. Mr. Rutherfurd invents an instrument which gives us the best photographs of the moon ever made. The Washington Observatory discovers the two satellites of Mars. Prof. Langley, in the midst of Pittsburg smoke, has made observations with instruments of his own invention, with an account of which he is now arousing great interest among the men of science of England. Dr. Peters, of Clinton, N.Y., and Prof. Watson, of Ann Arbor, have been the chief discoverers of the asteroids. Prof. Young and Harkness first gave, in 1869, the true theory of the solar corona. The two Bonds, at the Cambridge Observatory, have taken rank among the chief astronomers of our time. Our friend, Prof. Pickering, amid all his other labours, has invented instruments of precision by which the light of the stars can be measured with accuracy. And now we welcome home Dr. Gould, who has given long years of labour in a far-off land, away from home and friends, to complete his great work of a catalogue of the southern stars. To him and to his noble wife who shared his labours, sustained his courage, was his companion in his sacrifices, we give our thanks and our love to-night. We sympathise with him in that great loss, and we thank God with him that he and she had this great opportunity, and that they were able to share together, side by side, the consciousness of doing a work which will never be forgotten."

Other tributes were paid to the work of Dr. Gould by Prof. Lovering, of Harvard, Prof. Pickering, of Harvard Observatory, Dr. William Everett, Prof. W. A. Rogers, of Harvard. The last-named said that there is no exaggeration in the statement that the work which Dr. Gould has accomplished during the past thirteen years is without a parallel in the annals of astronomy.

"First of all it needs to be said that in 1870 there was no Cordoba Observatory. I suspect, also, that it must be said that astronomers had at that time little faith in the fulfilment of plans which required that the Government of a South American Republic should persistently pursue, for a series of years, that wise, enlightened and liberal policy which has made the Argentine Republic a conspicuous example of the way in which a government may foster learning and research with the most encouraging results. I do not know of a better way to give a clear idea of the magnitude of this work than by comparing it with similar work done previous to 1872. There are in the northern heavens, between the north pole and a little distance below the equator, about 4500 stars visible to the naked eye. These stars have been observed with more or less regularity at various observatories since about 1750. Within the same limits there are about 95,000 stars as bright or brighter than the ninth magnitude, which are usually observed in narrow belts or zones, and such stars are usually referred to as zone stars. The bright stars are common to nearly all general catalogues, but the positions of the fainter stars depend for the most part on two or three separate observations. Dr. Gould has formed two catalogues since 1872 —a general catalogue of stars extending to the south pole, containing 34,000 stars, and a catalogue of zone stars, numbering 73,000. These two catalogues represent about 250,000 separate observations. It is stated in one of the printed volumes that the chronographic register of the transits, the pointing of the telescope for declination, and the estimation of the magnitude have all been done by Dr. Gould personally. The distinct and separate observations involved in this work must certainly exceed 1,000,000. I suppose there must be several gentlemen present who have a realising sense of what a million really means, but for myself I commonly say that it seems to me to be a very large number. Having made less than 50,000 observations during the time covered by Dr. Gould's observations, can you wonder that this work, which seems so far beyond the limit of human endurance, is at once my amazement, my admiration, and—I must add—my despair? The whole number of stars in the two Cordoba catalogues is nearly three times as great as in any single catalogue thus far constructed; and it must be remembered in this connection, that the great catalogues of Lalande, of Bessel, of Argelander, and of Schjellerup, represent the labours of a life-time. The total number of stars in all catalogues formed previous to 1870, is about 260,000 as against the 105,000 stars in the Cordoba catalogues. But there is another comparison which may be made, which will reveal yet more clearly, not only the magnitude of the work which Dr. Gould has now finished, but the intense energy with which it has been pushed to completion. Since 1869 a confederation of fourteen observatories, situated in different parts of the world, has been engaged in the accurate determinations of the positions of the 100,000 stars to the ninth magnitude, in the northern heavens. Up to 1882 a total of about 346,000 observations had been made. Considerable progress had been made in this work before Dr. Gould left this country for South America. His work, involving two-thirds as many observations as all others combined, is completed, and is all in the hands of the printer, while the actual formation of the catalogue to be issued under the direction of the Astronomische Gesellschaft can hardly be said to have been begun."

TELPHERAGE

ON Saturday, October 17, a special train from Victoria conveyed a party of about 200 guests, among whom were many leading electricians, engineers, and other well-known men of science, to Glynde, in Sussex, to witness the ceremony of the opening of the first telpher line erected in this country. The ceremony was performed by the Viscountess Hampden, and was of an exceedingly simple character; on lifting a small box containing a present which the Chairman of the Company invited her ladyship to accept, electric communication was instantly established between the dynamo in the engine-house and the telpher line, and a train loaded with clay at once began to move up an incline towards the Glynde Railway Station, amidst the applause of the assembled spectators. Whether this ceremony, which brought so many distinguished visitors down to Lord Hampden's estate on Saturday, is the inauguration of a great commercial enterprise is beyond our province to inquire; but it is unquestionable that the slight flash seen when Lady Hampden lifted the little box lying on the table in front of the engine-house marked the beginning of a new departure in electro-technology.

Telpherage has been defined as the transmission of goods and passengers by means of electricity without driver, guard, signalmen, or attendants. The conception of propelling electrically a continuous stream of light trains along an elevated *single* rail or rope was due to the late Prof. Fleeming Jenkin, but, as stated by him in his introductory address at the University of Edinburgh, he did not see his way to carry this conception into practice until he read the account of the electrical railway exhibited by Professors Ayrton and Perry at the Royal Institution in 1882, when the idea of subdividing the rubbed conductor into sections and providing an *absolute block* for automatically preventing electric trains running into one another was first publicly described. A combination between these three gentlemen was then effected, which led ultimately to the formation of the Telpherage

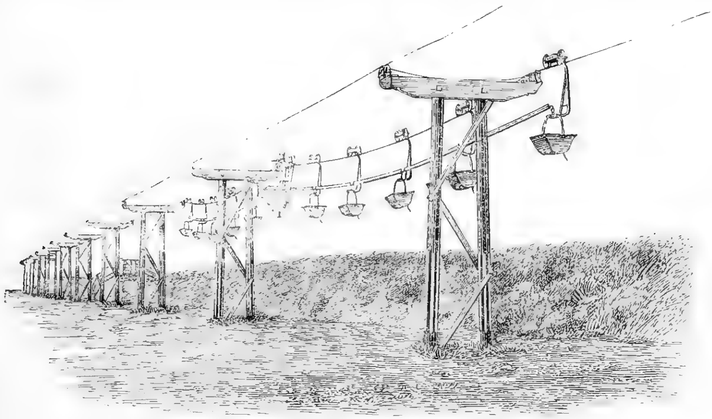

Fig. 1.

Company and to the series of experiments, lasting for over two years, on actual telpher lines erected at Weston in Hertfordshire, on the estate of Mr. Pryor, the chairman of the company. Various devices were worked out forming the subject of patents, which, together with the other patents of Professors Fleeming Jenkin, Ayrton, and Perry in telpherage, previously taken out, are possessed by the present Telpherage Company. At the commencement of this year matters had sufficiently advanced for the erection of commercial telpher lines, and as a tramway or road would have much interfered with the grazing and hay growing carried on in the fields at Glynde, and, as in addition these fields are under water during the winter, telpherage appeared to furnish the cheapest and most suitable mode of carrying the clay from the clay pits to the London, Brighton, and South Coast Railway. Con-

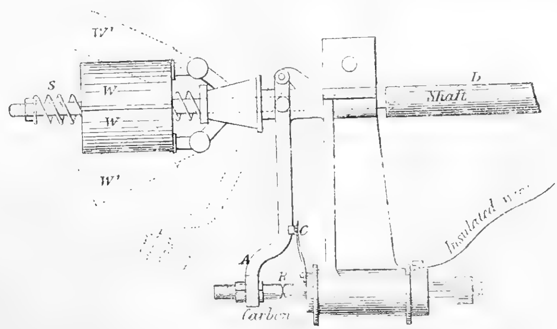

Fig. 2.

sequently the Sussex Portland Cement Company decided to adopt this method of transport.

The line now opened is nearly a mile long, and composed of a double set of steel rods each 66 feet long, three-quarters of an inch in diameter, and 8 feet apart, supported on wooden posts standing about 18 feet above the ground, as seen in our illustration (Fig. 1), which is from a photograph taken of the line just before it crosses the stream. On the death of the late lamented Prof. Jenkin the construction of the Glynde telpher line was left for completion in the hands of Prof. Perry, who was then appointed the engineer to the company. The new line, it must be understood, is more than a mere experimental attempt. Although, as scientific men will appreciate, a new undertaking must necessarily involve much tentative experience, the programme carried out on Saturday marked the final result of the experiences gained by the constructors under the direction of Prof. Perry, and the Company are now regularly delivering clay at the Glynde Railway Station for the use of the Newhaven Cement Company at a price, as we are informed, of $7\frac{1}{2}d.$ per ton.

The garlanded train which passed along the steel rodway on Saturday consisted of an electric locomotive, seen in Fig. 1 at about the middle of the train and propelled by the electromotor M, and ten skeps, or buckets, which hang by their travelling wheels from the steel line. Each skep weighs 101 lbs., and carries 250 to 300 lbs. of dry clay, and, by distributing these evenly and somewhat widely

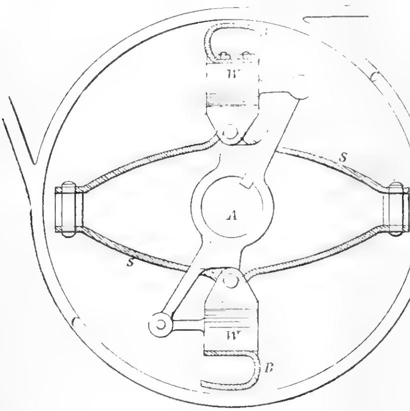

Fig. 2.

apart, the strain on the steel line is small although the total weight of the train and clay is about two tons, also as equal weights are simultaneously ascending and descending similar inclines on the several spans the effect of the sag on the mechanical resistance of the train is neutralised, and little more resistance is experienced than in hauling a similar train along a rigid road. The rate of travelling is 4 to 5 miles an hour about two electric horsepower only being necessary to be furnished at the engine-house to propel the train at this speed, and the train is under the control of a workman, who, by touching a key, can start, stop, or reverse the train at pleasure. On the arrival of each telpher train at the railway siding the clay is emptied into the railway waggons by the skeps being tipped over, this being effected either by a man touching with a pole the handles which are seen in Fig. 1 hanging down from the skeps, or automatically by these handles coming successively into contact with a wooden arm padded with india-rubber which is made to stand out from the post where it is desired the clay is to be emptied. One train will deliver the minimum amount of clay (150 tons per week) required by the Cement Company, but, if necessary, twenty trains can be run on the line without fear of a collision as an absolute automatic block is provided, and the trains are, moreover, governed automatically so as to run up or down an incline at the same speed.

This automatic governing of the speed of the train is effected in two ways—first, there is a governor attached to each motor, which interrupts the electric circuit, and cuts off the power when the speed becomes too high; secondly, there is a brake which is brought into action should the speed attain a still higher value. To avoid the formation of a permanent electric arc when the circuit is broken, the governor (Fig. 2) is so arranged that the diverging weights are in *unstable* equilibrium between two stops—they fly out at about 1700 revolutions per minute of the motor, and fly back at about 1600. When the circuit is closed the current is conveyed across the metallic contact at C. When the weights W W fly out this contact is first broken, but no spark occurs because a connection of small resistance is continued at B between the piece of carbon and a piece of steel, which being pressed out by a spring follows the carbon for a short distance as the arm A begins to fly out. This contact is next broken, producing an electric arc, which however is instantly extinguished by the lever A flying out to the dotted position. The brake is shown on Fig. 3, and consists simply of a pair of weights, W W, which at a limiting speed greater than 1700 revolutions per minute of the motor press the brake blocks B B against the rim C C, and introduce the necessary amount of retarding friction. In practice, however, with the gradients such as exist at Glynde, and which do not exceed 1 in 13, the economic method of automatically cutting off the power with the governor is all that is necessary to control the speed of the train; the brake rarely coming into action. With steeper gradients, however, the brake would undoubtedly be very useful.

The current required is 8 amperes per train, this current being measured by an ammeter in the engine-house, and by roughly timing the intervals when no current is being given to a train, that is, when the governor is acting, the particular hill the train is descending can be electrically determined by practice, and so the progress of a train

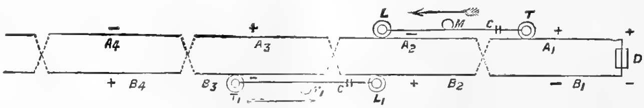

Fig. 4.

along the telpher line can be approximately followed by simply watching the ammeter in the engine-house. The electric current is supplied from a 200-volt dynamo driven by a steam-engine, and controlled by a Willans electric governor which automatically varies the speed of the engine and dynamo so as always to keep the electromotive force at 200 volts whatever be the number of trains running; hence the starting or stopping of one telpher train in no way affects the speed of the remainder. It is obvious that water-power or any other source of power can be used where available, even when the source of power is at a considerable distance from the line. By means of compensating gear the tension of the line is so regulated that it can never exceed $2\frac{1}{4}$ tons on each rod, whatever the temperature, and for straining the steel rods, when first erected, up to the right tension an ingenious arrangement has been devised during the construction of the line of vibrating them and determining the strain on a rod from the number of vibrations it makes per minute.

The way in which a single wheel track is made to serve for one train, or rather two wheel tracks for two trains, instead of the necessity of having four wheel tracks for two trains, as in the ordinary electric railways, is seen from Fig. 4. D is the dynamo maintaining two long conductors permanently at different potentials indicated by the signs + and − of each section. The wheels L and T of one train, and L_1 and T_1 of the other, are insulated from their trucks and joined by a conductor attached respectively to the terminals of the motor M and M_1. A current consequently is always passing from a + section to a − section through each motor. Mechanically then each train is supported by what is practically one continuous steel rod, but in reality at the tops of the posts the rods are electrically subdivided into sections and joined across by insulated wires, one of which may be seen at the top of the posts in Fig. 1. The wires connecting the two skeps with the motor, shown in Fig. 4, are not seen in Fig. 1, as they were too thin to appear in the photograph from which this figure was taken. To prevent the metallic wheels of the skeps short circuiting the two sections as they cross the tops of the posts, there are insulated gap pieces, which may be seen in Fig. 1, at the tops of the posts where the steel rod is electrically divided.

Various devices have been tried for gripping the rod to obtain the hold necessary to enable the locomotive to haul the train, and these, with many ingenious plans of *nest gearing* for economically communicating the power given out by the very quickly revolving electro-motor to the much more slowly moving wheels of the telpher locomotive, formed the subject of Prof. Jenkin's lecture at the Society of Arts in the spring of 1884. Practically, however, it is found that for moderate inclines direct driving, with pitch chains, of two wheels with india-rubber treads gives a gravitation grip sufficiently large for satisfactory haulage; hence the expense of the locomotive, the complexity and wear and tear of its parts combined with the risk of its getting out of order have been all most materially reduced during the last twelve months.

As the result of the experience gained in the construction of the Glynde line, it is estimated that a similar line could now be erected at short notice for a total cost of 1200*l.*, including engine, dynamo, permanent way, and five trains, with locomotives to carry 100 tons daily; the working expenses, including coal, attendance, and depreciation, being less than 3*d.* per ton per mile upon the material carried. A double line like that at Glynde, ten miles long, worked heavily, would carry material at a cost of 2*d.* per ton per mile, the skeps being empty on their return journey. The larger part of the original cost of the Telpher line is due to dynamos and rolling stock. This plant can be increased, as we are informed, in proportion to the work required, so that there is a very moderate increase of cost in the rate per ton per mile for a small traffic, as compared with a larger one. On the other hand, a line constructed for a small traffic will accommodate a much larger one with no fresh outlay on the line itself.

Leaving these facts and figures to speak for themselves, it now only remains to point out the advantages claimed for this system of electric carriage. In the first place the facility with which such a line can be run up and carried over uneven ground or across streams, high fences, and deep ditches, where an ordinary railway would involve serious expense, is sufficiently obvious. A Telpher line need not, as a railway necessarily does, impede the ordinary agricultural operations, but may be carried over fields and pasture lands with little inconvenience. The Telpher line is, moreover, in itself a source of power which can be simultaneously tapped at any desired points and made to assist in the work of agriculture, as the visitors on Saturday had an opportunity of witnessing when, by means of a motor connected with the line, a turnip-cutter was put into operation. The possibility of utilising natural sources of power like falling water, and of working the line at great distances from such sources will, as already stated, be evident to our readers. A special advantage claimed for the new system is the ease with which the trains can go round sharp curves without loss of power, since electricity, having no momentum, experiences no loss in going round a corner, whereas, with the overhead wire haulage system, as used in Spain and elsewhere, there is both considerable friction and great wear and tear of the running wire ropes where they go round sharp curves.

The constructors of the Glynde Line are careful to point out that the present line is far from perfect; unnecessary gradients have been introduced in order to show how the system can be carried over uneven land, and many other improvements have suggested themselves in the course of their experience, of which advantage would be taken in future undertakings. In face of these disadvantages, the success which marked Saturday's proceedings renders Telpherage, as a system, a very hopeful and cheap method of transference, and the Company is to be congratulated in having taken the first initiative step in this new application of electricity. That Telpherage will ever come into serious competition with the large railways is not intended, for the statement made by the Company is to the effect that the function of the Telpher line is not to compete with railways, but to do cheaply the work of horses and carts, light tramways, and the wire rope haulage system, and this, we think, it has a good chance of successfully accomplishing.

THE MELDOMETER

THE apparatus which I propose to call by the above name (μέλδω, to melt) consists of an adjunct to the mineralogical microscope, whereby the melting points of minerals may be compared or approximately determined and their behaviour watched at high temperatures either alone or in the presence of reagents.

As I now use it it consists of a narrow ribbon of platinum (2mm. wide) arranged to traverse the field of the microscope. The ribbon, clamped in two brass clamps so as to be readily renewable, passes bridgewise over a little scooped-out hollow in a disk of ebony (4 cm. diam.). The clamps also take wires from a battery (3 Groves cells), and an adjustable resistance being placed in circuit the strip can be thus raised in temperature up to the melting point of platinum.

The disk being placed on the stage of the microscope the platinum strip is brought into the field of a 1″ objective, protected by a glass slip from the radiant heat. The observer is sheltered from the intense light at high temperatures by a wedge of tinted glass, which further can be used in photometrically estimating the temperature by using it to obtain extinction of the field. Once for all approximate estimations of the temperature of the field might be made in terms of the resistance of the platinum strip, the variation of such resistance with rise of temperature being known. Such observations being made on a suitably protected strip might be compared with the wedge readings, the latter being then used for ready determinations. Want of time has hindered me from making such observation up to this.

The mineral to be experimented on is placed in small fragments near the centre of the platinum ribbon, and closely watched while the current is increased, till the melting point of the substance is apparent. Up to the present I have only used it comparatively, laying fragments of different fusibilities near the specimen. In this way I have melted beryl, orthoclase, and quartz. I was much surprised to find the last mineral melt below the melting-point of platinum. I have, however, by me as I write, a fragment, formerly clear rock-crystal, so completely fused that between crossed Nicols it behaves as if an amorphous body, save in the very centre where a speck of flashing colour reveals the remains of molecular symmetry. Bubbles have formed in the surrounding glass.

Orthoclase becomes a clear glass filled with bubbles:—at a lower temperature beryl behaves in the same way.

Topaz whitens to a milky glass—apparently decomposing, throwing out filmy threads of clear glass and bubbles of glass which break, liberating a gas (fluorine?) which, attacking the white-hot platinum, causes rings of colour to appear round the specimen. I have now been using the apparatus for nearly a month, and in its earliest days it led me right in the diagnosis of a microscopical mineral, iolite, not before found in our Irish granite, I think. The unlooked-for characters of the mineral, coupled with the extreme minuteness of the crystals, led me previously astray, until my meldometer fixed its fusibility for me as far above the suspected bodies.

Carbon slips were at first used, as I was unaware of the capabilities of platinum.

A form of the apparatus adapted, at Prof. Fitzgerald's suggestion, to fit into the lantern for projection on the screen has been made for me by Yeates. In this form the heated conductor passes both below and above the specimen, which is regarded from a horizontal direction.

J. JOLY

Physical Laboratory, Trinity College, Dublin, November 1

NOTES

OUR readers will hear with regret that Prof. Huxley has placed in the hands of the Council of the Royal Society his resignation of the office of President, and that the Council have felt it their duty to accept that resignation. It would appear that Prof. Huxley had wished to resign so long ago as November last, when he had decided to winter abroad, and again, last summer, he definitely placed his resignation in the hands of the Council. On both these former occasions Prof. Huxley was induced to continue in office, in the hopes that he would soon regain complete health. On the present occasion we gather that the resignation was accepted, because, though Prof. Huxley is rapidly improving in health, the cares of the presidential chair seemed likely to prove a hindrance to his complete recovery being so rapid as could be desired. We feel sure that the whole scientific world will share the regret of the Council of the Royal Society at the necessity of such a step, but we also feel that every one must recognise the wisdom of the decision. We may add that every one hopes that freedom from the responsibilities of office may soon convert the marked improvement in Prof. Huxley's health, visible to all his friends, into complete and perfect restoration.

WE understand that Prof. Stokes has consented to allow himself to be nominated as Prof. Huxley's successor in the presidential chair. We believe that this choice of the Council will give universal satisfaction to the Fellows of the Society; while it makes Prof. Stokes doubly the successor of Newton, it does honour to the Society.

A CONSIDERABLE portion of the "Zoological Record" for 1884 has already been issued to subscribers; the Reports on Coleoptera, Lepidoptera, and Hymenoptera, by Mr. W. F. Kirby, were issued in September, and those on Reptiles, Fishes, Mollusca, Tunicata, Polyzoa, and Brachiopoda last week. The remaining parts are in a very forward state, Mr. W. L. Sclater, B.A., having undertaken the Mammalia in the place of Dr. Murie.

THE French Government has just created a certain number of travelling-juries. This is a modified form of an institution established by the first Republic. In the organic law of the Institut it was ordained that the Institut was to select yearly ten citizens to travel abroad and collect information useful to science, commerce, and agriculture. These scientific travellers will not be appointed by the Academy of Sciences or the whole Institut, but by a special administrative commission on the basis of a competitive examination.

WHILE so much public attention is attracted by the second part of the Greville "Memoirs," it will interest our readers to learn that the acute and observant Clerk to the Council, who, on the whole, had a very low idea of the great men with whom he came in contact, possessed a great respect for the men of science of his generation. Under March 17, 1838, we find the following interesting entry ("Memoirs," vol. i. p. 78):—"Went to the Royal Institution last night in hopes of hearing Faraday lecture, but the lecture was given by Mr. Pereira upon crystals, a subject of which he appeared to be master, to judge by his facility and fluency; but the whole of it was unintelligible to me. Met Dr. Buckland and talked to him for an hour, and he introduced me to Mr. Wheatstone, the inventor of the electric telegraph, of the progress of which he gave us an account. I wish I had turned my attention to these things and sought occupation and amusement in them long ago. I am satisfied that, apart from all considerations of utility, or even of profit, they afford a very pregnant source of pleasure and gratification. There is a cheerfulness, an activity, an appearance of satisfaction in the conversation and demeanour of scientific men that conveys a lively notion of the *pleasure* they derive from their pursuits. I feel ashamed to go among such people when I compare their lives with my own, their knowledge with my ignorance, their brisk and active intellects with my dull and sluggish mind, become sluggish and feeble for want of exercise and care."

THE first volume of "Geology, Chemical, Physical, and Stratigraphical," by Prof. Joseph Prestwich, F.R.S., will be ready for publication immediately by the Clarendon Press. This work is a general treatise on Geology adapted both for elementary and advanced students. Vol. I. treats of questions in chemical and physical geology, and special attention is paid to such subjects, among others, as Hydro-Geology, the geological bearings of the recent deep-sea explorations, volcanic action, joints, mineral veins, the age of mountain ranges, and metamorphism. Vol. II., which is far advanced, treats of stratigraphy and palæontology, and touches upon various theoretical questions. The author advocates the *non-uniformitarian* views of geology. The book is copiously illustrated with woodcuts, maps, and plates.

FATHER DENZA, according to the *Times* Rome correspondent, writing from the Observatory of Moncalieri, gives interesting particulars of a remarkable shower of dust which fell in various parts of Italy in the night of October 14–15. This dust-shower accompanied the violent gale of wind which occurred at the time, and seems to have fallen thickest in places situated more or less in the latitude of Rome. Father Denza regards the dust as meteoric. Mr. Abercromby writes to the *Times* to point out that this is probably premature, if by meteoric Father Denza means the product of meteors. But is it not probable that by meteoric sand he simply means sand which falls as "a meteor" or meteorological phenomenon? As Mr. Abercromby points out, this dust probably came from the Sahara.

AN interesting series of papers, copiously illustrated by charts, and comparative tables, is appearing in *Naturen*, on the climate of Norway. The author, Dr. Hesselberg, enters fully into the various causes on which depend the great differences between the inland and littoral climates, and notes in detail the varying relations of temperature for each month in the interior, and on the coast. From these tables it would appear that while in Norway, generally, the five months, from November to March inclusive, exhibit a purely winter temperature, no single month presents throughout a complete summer temperature. The remaining four months pass through the various stages of temperature between winter and summer. In the more northern and more elevated parts of the interior not a single month of the year is free from the risk of night-frost, while in such localities frost occurs on from 225 to 230 days in the year. On the coastlands, on the other hand, the mean winter temperature is generally from 2° to 3° Cels. above the freezing point, and here the greatest cold occurs in February, while in the interior December and January are the coldest months.

WE learn, from a recent report by Herr Reusch, of the condition of the Bommelö gold-mines worked by Messrs. Oscar and Daw, that gold to the value of 8000 kroner has been obtained during the three months in which these works have been in operation. The writer believes the mines may be made remunerative, but only moderately so, and provided they are worked with care and economy, and he emphatically warns his countrymen not to waste time and money, as has frequently been done in Norway, in seeking for gold in localities where the existence of any appreciable quantity of quartz is not well attested beforehand. He, moreover, points out the fallacy of believing that any large proportion of the auriferous quartz deposits of Norway are capable of yielding more than the mere fragmentary traces which are so constantly met with. Quite recently, indeed, the presence of gold has been shown in new localities, Herr Hansen having obtained in the quartz at Haugesund a number of microscopically small granules of the precious metal with titanic iron, while at Mæland, in Bommelö, about four miles from the spot where the first finds were made, he extracted gold after crushing and washing the white quartz which occurs in large lumps, accumulated on a hillock about 5 feet high, by 36 in length, and 13 in breadth.

PÈRE DECHEVRENS, the head of the Zi-ka-wei Observatory near Shanghai, has published a pamphlet entitled, "The Meteorological Elements of the Climate of Shanghai: Twelve Years of Observations made at Zi-ka-wei by the Missionaries of the Society of Jesus." It is a series of tables containing "all the information that meteorology can supply concerning the climate of Shanghai." A complete meteorological period in China is said to be about eleven years, and consequently this pamphlet embraces one such period. The tables show maximum and minimum, mean and normal readings of the barometer and thermometer, intensity of solar radiation, relative and absolute humidity, nebulosity, rainfall, and direction and velocity of the wind for every month throughout the twelve years, conveniently tabulated for comparison. There is also a table of eight years' observations of ozone, and a special section is devoted to terrestrial magnetism. Explanations are given in most cases of the methods of taking the various observations, and the objects which they serve. The readings are all given according to English methods of computation; but for the convenience of those who are more familiar with the metric barometer scale and the centigrade degrees of temperature, tables for the conversion of the English into the Continental systems are given.

AMONGST the anthropological papers recently issued by the Smithsonian Institution, special interest attaches to the memoir by Lieut. C. E. Vreeland and Dr. J. F. Brandsford on the antiquities recently discovered on the Pantaleon estate, near Santa Lucia, Guatemala. This place, which lies about thirty miles north-west of Escuintla on the railway from San José to the city of Guatemala, was visited in 1884 by the authors for the purpose of photographing the objects, which had here been observed two years previously by Dr. Brandsford, and earlier by Dr. Habel. Several of the finest specimens had been removed to Berlin, where an account of them was published by Dr. Adolph Bastian. Those here described and figured from the photographs form a group of remarkable sculptures, all of black basalt or hard lava mounted on a low wall round the fountain of the Pantaleon courtyard, and disposed in front of a grand central piece raised on a pedestal. This figure, which is in an excellent state of preservation, the nose alone being injured, is a new revelation in native American art, characterised by great strength and simplicity of outline. It is well formed, the lines simple and clearly cut, without a trace of the usual conventional style. Majesty is so plainly stamped on the countenance, that it was known to the Indians by the name of El Rey—the king. The brow, the eyes, and the nose, as far as can be judged, are in good shape and well proportioned; the mouth hard, the chin firm and full of character. Near it stands the head of an old person whose venerable appearance is heightened by the deep lines on brow and cheek. In contrast to this is another head of an old person, where calmness of expression is replaced by the inexpressible sadness of age with blindness. As in the case of some other figures, the eyes are here represented as hanging from the sockets, the balls resting on the cheeks. The chin and lower lip protrude, while the upper lip has fallen in as from the loss of teeth. To the long ears are appended large pear-shaped ornaments, and the turban-like headdress is surmounted with a little Tam O'Shanter cap. All the figures show real artistic skill, far beyond the elaborate but fantastic style of the conventional sculptures found at Copan and other parts of Central America.

A BORE-HOLE made about two years ago to a depth of 52 metres into the older Devonian strata near Burgbrohl on the Rhine, yields a large and steady supply of carbonic acid gas (with water) which is variously utilised. In a recent paper to the Niederrheinische Gesellschaft in Bonn, Herr Heusler says the normal quantity of gas amounts to about 2160 cubic metres in twenty-four hours. The supply having proved constant, a compressing apparatus was set up last autumn; the gas being taken directly over the bore hole. The present system produces per minute from 500 litres of gaseous $C.O_2$., 1 litre of liquid, weighing 1 kilogram. As the liquefaction depends on the external air-temperature, and is impossible at a temperature over 30·9 C. (the critical point), it is necessary in high temperatures to cool the apparatus, and the water of the spring (which keeps at 12°) serves for this. The pressure employed ranges from about 50 to 70 atmospheres. The wrought-iron vessels for despatch of the liquid contained about 8 litres, or 8 kilograms, and are tested to about 250 atmospheres; they very rarely explode. The enormous expansion of carbonic acid with rise of temperature yields a pressure which is utilised, it is known, for compression of steel and other casts, and Messrs. Krupp at Essen have thus got, *e.g.* a pressure of 1200 atmospheres for a temperature rise of 200° C. Among other rises are pressure of beer, impregnation of natural water, apparatus for fire extinction, motor force for torpedoes, &c. Solid carbonic acid is to a large extent produced from liquid by opening the cock of the vessel into a canvass bag tied over the mouth.

IN his recent investigation of pile-dwellings of the Lake of Bienne, Dr. Studer has met with two extreme types of human skulls—the brachycephalic and the dolichocephalic; the former (at Schaffis and Lüschery) belonging to the pure Stone period, and the latter (found at Vinelz and Sutz) to the Bronze period. The facts point to an invasion by the bronze men, involving a complete transformation of the group of domestic animals; the horse appears for the first time, and new races of sheep and dogs drive out the old forms of the Stone period. The occurrence of mesocephalic, and even much shortened, skulls in the Bronze period shows that there was no extinction of the brachycephalic race, but that the two races mixed. This mixture of races in prehistoric times increases the difficulty of tracing back the skull-forms of the present population. Dr. Studer suggests that the Rhaetian short-headed type may be referred to the old dwellers of the Stone period, in which case the prevalent dark hair, eyes, and skin of the present natives of Graübünden may recall the aspect of the older prehistoric race. There is also a large dark population about the lakes in Canton Berne.

M. VERNET has recently made a number of physiological observations on himself during eighteen ascents of high Alpine summits (between 1680 and 4638 metres in height). He finds that the strong muscular efforts made both in mounting and descending caused a rise of temperature of about 1·64° to 1·70° C. on an average; a rise in the pulse from about 75 to 83 in a minute, and an increase in the respiratory acts from about 21 to 25 in a minute. A few hours' rest after the effort ceased brought back the temperature to its normal value. Other muscular efforts, such as riding, wood-sawing or chopping, &c., had quite the same effect. The author's observations are detailed in the *Archives des Sciences*.

THE School of Anthropology, created a few years ago under the auspices of the city of Paris, has opened its 1885–86 session. The course of lectures delivered by M. de Mortillet on prehistoric anthropology will be illustrated for the first time by a series of projections. English anthropologists will learn with pleasure that M. Gabriel de Mortillet, who was one of the companions of Agassiz, has been elected representative of the Seine et Oise Department.

THE engineers of the French Service are establishing a telephonic communication between Paris and Rheims, 160 kilometres from Paris. The Paris terminus of this line will be the Exchange. A sum of one franc for each five minutes will be charged for conversation. As soon as this line is finished the work will begin of connecting Rouen with Paris (126 kilometres). Rouen has been already connected with Havre, 78 kilometres distant, by a telephonic line. Conversation between these two cities is very easily held. It is the success of this system which led to further extension on larger distances.

ON October 9, between 9 and 10 a.m., two severe shocks of earthquake were felt on the Lis Island, in the parish of Sorunda, in Sweden. In the school-house, while teaching was going on, two severe shocks were felt like two blows from an enormous hammer in the north-western corner of the building. In this corner the windows rattled, the floor swayed, and rumbling like that of distant thunder was heard. Simultaneously a great thunderstorm passed over the district, accompanied by heavy rain. It has, however, been ascertained beyond doubt that the shocks were not due to the former, as the shocks were felt by many persons out of doors. The earthquake went from west to east.

SINCE 1880, when diggings for amber were commenced under the Smaland Peninsula in East Prussia, the yield of the veins here has greatly increased. In 1864 the revenue was 1700*l*. against 25,000*l*. in 1883.

MR. WILLIAM CAMERON, F.G.S., the Singapore papers state, has been appointed *Honorary* Explorer and Geologist to the Straits Settlements. "Honorary Explorer" is a curious office, and we cannot recollect ever having heard of one before; but as Mr. Cameron, it is to be presumed, has accepted these two honorary offices, they must be of some assistance to him in his explorations in the Malay Peninsula. One so rarely hears of an Honorary Colonial governor, secretary, treasurer, or other official, that an "Honorary Colonial Explorer" is something of a *rara avis*, and as such deserves to be specially chronicled.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂), a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Mr. C. E. McCheane; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. C. Canfor; a Mexican Deer (*Cariacus mexicanus* ♂) from Florida, presented by Mr. G. B. H. Marton; two Spotted-tailed Dasyures (*Dasyurus maculatus* ♂ ♀), three Short-headed Phalangers (*Belideus breviceps* ♂ ♂ ♀) from South Australia, presented by Sir W. C. F. Robinson, K.C.M.G.; an Osprey (*Pandion haliaetus*), captured at sea, presented by Capt. Morgan; an Alexandrine Parrakeet (*Palaeornis alexandri*) from India, presented by Mr. Chas. Williams; a Black-eyebrowed Albatross (*Diomedea melanophrys*) from False Bay, South Africa, a Vulturine Eagle (*Aquila verreauxi*) from South Africa, a Sharp-headed Lizard (*Lacerta oxycephala*) from Madeira, presented by Mr. W. Ayshford Sandford, F.Z.S.; a Black-crested Eagle (*Lophoaetus occipitalis*) from South Africa, presented by the Lady Robinson: a Rufescent Snake (*Leptodira rufescens*), a Hoary Snake (*Coronella cana*), a Keeled Euprepes (*Euprepes carinatus*), five Rough-scaled Zonures (*Zonurus corydlus*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; three Grey-breasted Parrakeets (*Bolborhynchus monachus*) from South America, a Pale-headed Broadtail (*Platycercus pallidiceps*) from North-East Australia, deposited; two Lesser Vasa Parrakeets (*Coracopsis nigra*) from Madagascar, purchased.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, NOVEMBER 8–14

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 8

Sun rises, 7h. 8m.; souths, 11h. 43m. 54·1s.; sets, 16h. 20m.; decl. on meridian, 16° 43′ S.: Sidereal Time at Sunset, 19h. 32m.

Moon (two days after New) rises, 8h. 28m.; souths, 13h. 9m.; sets, 17h. 46m.; decl. on meridian, 16° 33′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	8 34	12 38	16 42	21 42 S.
Venus	11 22	14 54	18 26	26 12 S.
Mars	23 48*	7 0	14 12	13 11 N.
Jupiter	2 34	8 46	14 58	1 33 N.
Saturn	19 17*	3 25	11 33	22 18 N.

* Indicates that the rising is that of the preceding day.

OPTICAL THEORIES[1]

THE last general report on Optics which was laid before the Association was read at Dublin by the late Dr. Lloyd in the year 1834, fifty-one years ago. Since then, in 1862, Prof. Stokes dealt very completely with double refraction so far as the elastic-solid theory is concerned, and there is little to add to what he said then. In all branches of his subject the fifty-one years since Dr. Lloyd's report have been most fruitful, and in consequence the mass of papers to be dealt with has been very large.

The report is divided into four sections: the first, which is introductory, deals with the work of Green, MacCullagh, Cauchy, and Neumann, the founders of the elastic-solid theory.

In the second section the more modern writers on the elastic-

[1] Report presented to the British Association by R. T. Glazebrook, M.A., F.R.S.

solid theory are considered—De St. Venant, Sarrau, Lorenz, Stokes, Lord Rayleigh, Kirchhoff, and others.

The third section is devoted to theories in which the mutual action between the matter molecules of the transparent body and the ether is considered as the main cause of refraction, dispersion, and other phenomena.

The chief workers in this field seem to be Boussinesq, Sellmeier, Helmholtz, Lommel, Ketteler, Voigt, and, in his lectures at Baltimore, Sir W. Thomson.

The fourth and last section deals with the electro-magnetic theory of Maxwell, and the developments it has received from the hands of Helmholtz, H. A. Lorentz, Fitzgerald, J. J. Thomson, Rowland, and Glazebrook.

The report is devoted strictly to *general optical theories*. This has been required by the necessities of both space and time, and, as a consequence, the optical papers of many most distinguished workers, such as Fizeau, Jamin, and Quincke, are hardly noticed, except in so far as the results at which they have arrived bear on some point or other of the general theory. There is ample room for a report dealing with optics from an experimental standpoint which should arrange and compare the conclusions of various experimenters on debated points.

Turning, then, to the sections in order: in the second section, which deals with the elastic-solid theory, the optical properties of media are considered on the hypothesis that they arise entirely from differences in the rigidity or in the density of the ether in these media.

While the development of this theory has taught us much, we are driven to conclude that the fundamental hypothesis will not account for all the optical phenomena.

The papers of Stokes on diffraction, of L. Lorenz and Lord Rayleigh on refraction and the scattering of light by small particles, have proved conclusively that we must look to difference of density, or of apparent density, in the media to explain the phenomena, and not, as was suggested by MacCullagh and Neumann, to difference of rigidity.

With this conclusion Fresnel's hypothesis that the direction of vibration in polarised light is normal to the plane of polarisation is necessarily connected.

On the other hand, the only strict elastic-solid theory of double refraction is that of Green, and according to it, if we suppose the medium initially free from stress, the direction of vibration lies in the plane of polarisation, and even this conclusion is only arrived at by supposing certain arbitrary relations between the coefficients.

These two conclusions, then, of the elastic-solid theory are hopelessly at variance. It is true that, by supposing the medium initially to be in a state of stress, Green arrived at a second theory in agreement with his theory of reflection, but this agreement is gained by the introduction of a second set of arbitrary relations.

In connection with this point I should mention that it seems to me that Green's theory of reflection can be reconciled with experiment by adopting the suggestions of Lord Rayleigh as to the refractive index of the media for the normal waves.

The elastic-solid theory also fails to explain anomalous dispersion and metallic reflection. Cauchy's expressions for the mathematical analysis of the latter agree with experiment; but then they require that μ^2 should be complex quantity with its real part negative, and this involves the instability of the medium as regards the problem of ordinary dispersion. Cauchy's theory has been advanced by the writings of Sarrau; while the investigations of Ketteler have shown that a formula of the form—

$$\mu^2 = A + B\lambda^2 + \frac{C}{\lambda^2} + \frac{D}{\lambda^4}$$

agrees very closely with experiment.

Stokes has given us an explanation of aberration by showing us that we may suppose the earth to move through space and carry the surrounding ether with it, the ether at some distance from it being at rest; provided that the motion thus produced in the ether be irrotational, all the known phenomena of aberration will follow. And he has further shown us that any small tendency to variation from such irrotational motion will call into action the rigidity of the ether, and be propagated into space with the velocity of light. According to the views developed in these papers of Prof. Stokes, the ether may be treated as a perfect fluid for the large motions produced in it by the motion of the earth; while at the same time it has rigidity, and obeys the equations of an elastic-solid for such small motions as are involved in the passage of a wave of light.

According to the views dealt with in the second section, the ether is of the same density and rigidity in all transparent media. For such media, however, its motions are affected by the presence of the molecules of the medium. Some of the energy of the incident light may be used up in setting these matter-molecules into motion. The amount required for this depends on the nature and properties of the matter-molecules, and hence is different for different media and for waves of different length. This gives rise to reflection and refraction.

There are indications in the writings of Fresnel that he looked to some explanation himself, but it seems to be to Boussinesq that we owe the first real development of the theory.

He forms the equation of motion of the ether and matter combined on the supposition that the forces on the matter arising from the direct action of surrounding matter are owing to the smallness of the displacements negligible. He then supposes that the matter displacement U may be expanded in terms of the ether displacements u and its differential coefficients, and finally arrives at equations of the form

$$(\rho + A\rho')\frac{d^2u}{dt^2} = B\,\Delta^2 u + C\frac{d\delta}{dx}, \text{ \&c.}$$

where

$$\delta = \frac{du}{dx} + \frac{dv}{dy} + \frac{dw}{dz}.$$

B and C involve the period, ρ is the density of the ether, and ρ' of the matter; and hence dispersion is accounted for. Double refraction is explained by supposing A to be a function of the direction, while B and C remain constant; and for this reasons are given, and it is shown that on certain other hypotheses this leads to Fresnel's theory. This theory deals also with the phenomena of elliptic polarisation in quartz, and of aberration.

In Boussinesq's theory the motions of the matter particles are neglected, except in so far as they act on the ether and modify its motion. Sellmeier was the first to see that reflection and refraction would be profoundly modified in the cases in which the free period of the matter particles agrees with that of the incident light, and when, therefore, the energy in that light is absorbed in setting the matter into motion. His work was continued by Helmholtz, Lommel, Ketteler, Voigt, and Sir W. Thomson.

The equations of motion employed by all these writers are the following:

$$\rho\frac{d^2u}{dt^2} = X + \bar{A} + X',$$

$$\rho'\frac{d^2U}{dt^2} = \Xi + A + \Xi'.$$

In these equations X represents the force on the ether, in the element of volume considered, arising from the surrounding ether; X', from any external impressed forces; and $\bar{A}$, from the matter; while Ξ, Ξ', and A, are the same for the matter. According to all $X = X' = 0$. We must also have $\bar{A} + A = 0$. The difference in the theories consists in the different forms given to A.

Sellmeier, Thomson, and Helmholtz put $A = \beta^2(u - U)$. Lommel puts $A = \beta^2\frac{d}{dt}(u - U)$. The results of Ketteler's theory are, except in one small and, I venture to think, non-essential point, identical with those found by putting $A = \beta^2\frac{d^2}{dt^2}(u - U)$ (Ketteler obtains his equations in a different form from the above). Voigt investigates the general form possible for A consistent with the propagation of a plane wave and the conservation of energy. He finds

$$A = \left(\alpha^2 + \beta^2\frac{d^2}{dt^2} + \gamma^2\frac{d^2}{dz^2} + \delta^2\frac{d^4}{dt^2\,dz^2}\right)(u - U).$$

For the value of X all the authors put—taking waves travelling parallel to z—

$$X = e\frac{d^2u}{dz^2};$$

while Voigt adds the term $\frac{dp}{dz}$. For Ξ all but Voigt and Thomson write—

$$\Xi = aU + b\frac{dU}{dt}.$$

Thomson objects to the term $\frac{dU}{dt}$ as involving a viscous expenditure of energy. Voigt argues, with Boussinesq that in ordinary transparent media U is so small compared with u that it may be neglected, and puts it zero everywhere.

The results of the various theories differ in the form they give for the dispersion formula. Lommel's theory has been shown by Voigt to be untenable. The theories of Helmholtz, Thomson, and Sellmeier lead, when b is small, to the same result, and give

$$\mu^2 = 1 + \frac{\beta^2 \tau^2}{\rho} \left\{ 1 + \Sigma \frac{q \tau^2}{\tau^2 - \kappa^2} \right\},$$

which Ketteler's gives

$$\mu^2 = 1 + \frac{\beta^2}{\rho} + \Sigma \frac{D}{\tau^2 - \kappa^2}.$$

τ is the period of the ether vibration, κ of the matter vibration, and q, D, &c., are functions of the constants.

Voigt's formula, since he does not consider the matter motion, is different and not so general.

With regard to these formulæ, I am not aware that Helmholtz's has been tested by comparison with experiment. Ketteler's has, and agrees excellently over a long range of values of τ.

Double refraction is generally explained by supposing β^2 to be a function of the direction; but, as Sir W. Thomson has pointed out, this involves for Helmholtz's theory—he did not, however, apply his formulæ to crystals—dispersion with double refraction. For Ketteler's theory this is not the case. μ can be a function of the direction independently of τ.

The mechanism which would make the action between the matter and ether in each element of volume a function of the acceleration is perhaps not so easy to conceive as that supposed by Helmholtz and Thomson; but still Ketteler's theory seems to overcome some of the difficulties inherent in the latter.

Either of these theories can be shown to lead to Fresnel's wave-surface, provided we do not consider it necessary that the vibrations should lie in the wave-front. The vibration, as indeed Ketteler and Boussinesq have pointed out, will be normal to the ray. In all other respects Fresnel's construction will hold.

Ketteler and Voigt have tried, without much success, to apply their theories to reflection and refraction.

Thomson, in that most valuable appendix to his Baltimore lectures, has given a complete theory. This can be readily adapted to Ketteler's theory, and the results in many points agree in a striking manner with experiments both for transparent and opaque bodies. The occurrence of a real negative value for μ^2 is explained by the supposition that the period of the incident light is higher than the highest possible mode of vibration for the matter-molecules in the medium.

The last section deals with Maxwell's electro-magnetic theory of light.

Electro-magnetic disturbance travels in air with a velocity equal to that of light; and in a double refracting medium obeys Fresnel's laws. The difficulty lies in giving a physical explanation of light motions, and of accounting for the mechanical structure of the ether required by the theory. No complete theory of dispersion has yet been given. The work of Willard Gibbs does not explain why there is no dispersion in a vacuum. The objection made to Cauchy's theory holds good. It is probable that some theory such as is developed in the third section may be successfully applied to the electro-magnetic disturbance.

The theory has the great advantage of connecting naturally with the theory of light the important electro and magneto-optical discoveries of Faraday, Kerr, Kundt, and Quincke, and to the development of this much is due to Prof. Fitzgerald. The theory of reflection and refraction as at present developed is only approximate.

ELECTROLYSIS

PROF. LODGE opened the discussion at the Aberdeen meeting of the British Association on Electrolysis by reading a paper, the notes of which have already appeared in NATURE.

Sir W. Thomson referred, in his remarks on Prof. Lodge's paper, to a matter of importance in electro-plating—viz. the selection which takes place in the electrolysis of solutions containing several salts, as, for instance, in the electrolysis of copper sulphate containing ferrous sulphate, which, when decomposed by a strong current gives a deposit containing impurities, whereas a slower decomposition yields a very pure deposit. Sir W. Thomson spoke also of the necessity for the careful investigation of those cases in which the formation of deposits between the electrodes had been observed, and it would be important to know whether deposits could be formed in the line of conduction without a nucleus at all. Such matters are of importance to physiology, indicating a possible danger in the passing of long continued currents through the human body.

Prof. Schuster explained the views propounded by Von Helmholtz in his recent papers on this subject. Helmholtz explains the phenomena of electrolysis by assuming a different attraction of different chemical elements for electricity. If this be admitted, most of the difficulties connected with the phenomena of contact electricity disappear. In electrolysis the element (say hydrogen) charged with positive electricity travels to the negative electrode and forms a coating over it. Any electromotive force, however small, is sufficient to produce this effect, as no work is done. The hydrogen does not appear as free hydrogen, however. It is only liberated when the electromotive force is sufficient to produce a transfer of the positive electricity from the hydrogen molecule to the electrode. When the dissociated elements appear in a neutral state an interchange of the electricities of the elements must have occurred before dissociation. In this way we may explain the conversion of stannic in stannous chloride, which was mentioned by Prof. Armstrong in his address. Prof. Schuster did not think that Prof. Lodge had laid sufficient stress on the fact that in very dilute solutions an ion has the same rate of transference, no matter with what element it was combined. This fact affords strong evidence in favour of the above views, from which it follows as a necessary result. Prof. Schuster also explained his own views of the discharge of electricity in gases. He believes that the phenomena present some analogy to those exhibited in electrolysis of liquids. The phenomena exhibited at the negative pole are, he thinks, due to dissociation of the compound molecule. They do not appear in the case of monatomic mercury vapour. Experiments which he hopes to conclude in the next few months will decide whether or not the law of the constancy of molecular charge holds.

The next contribution to the discussion was a paper by Dr. C. R. Alder Wright, containing an account of the nature of his investigations, conducted with the view of measuring Chemical Affinity in terms of E.M.F.

On the Sensitiveness to Light of Selenium and Sulphur Cells, by Shelford Bidwell, M.A., LL.B.—The author suggests that the operation of annealing in the making of selenium cells increases the sensitiveness to light by promoting the combination of the selenium with the metal of the electrodes, forming a selenide which completely surrounds the electrodes, and is, perhaps, diffused throughout the selenium when in a liquid condition; further, that the apparently improved conductivity of the selenium, together with the electrolytic phenomena which it exhibits, are to be accounted for by the existence of this selenide. This view finds considerable support in the fact that cells, constructed with sulphur, replacing the selenium and containing a proportion of silver sulphide, are all more or less sensitive to light, and exhibit properties of annealed selenium. The author also read a paper *On the Generation of a Voltaic Current by a Sulphur Cell with a Solid Electrolyte*, a short account of which has already appeared in NATURE (vol. xxxii. p. 345).

MOLECULAR WEIGHTS

THE discussion on the Molecular Weights of Liquids and solids was opened in Section B of the British Association by the reading of a paper by Prof. A. W. Reinold, F.R.S., the subject of which was the *Size of Molecules*. In this paper an account was given of the different lines of argument by which Sir W. Thomson has been led to form an estimate of the size of molecules. The estimate is based upon four lines of argument—the first, from the refractive dispersion of light; the second, from the phenomena of contact electricity; the third, from liquid films; and the fourth, from the kinetic theory of gases. All four agree in showing that in liquids and transparent solids the mean distance between the centre of contiguous molecules is something between 1/10th and 1/200th of a millionth of a millimetre. Recently Exner (*Monatschrift für Chemie*, vi. 244-278) has proposed another method for estimating the diameter of gaseous molecules, the results obtained by this method being slightly smaller than those deduced from the above. The author gave an account of his experiments on soap-films, conducted conjointly with Prof. Rucker (NATURE, vol. xxxii. p. 210), the results of which are not out of accord with Sir W. Thomson's estimate of the size of molecules.

On Macro-molecules, with the Determinations of the Form of some of them, by Prof. G. Johnstone Stoney, D.Sc., F.R.S.—The author suggested that the molecule of a crystal, which in all probability, consists of several chemical molecules, should be termed a macro-molecule. He then went on to show that it is possible to deduce the form of the macro-molecule from the composition of the chemical molecule ; this he illustrated by the cases of iron pyrites, boracite, and quartz.

An Approximate Determination of the Absolute Amount of the Weight of Chemical Atoms, by Prof. G. Johnstone Stoney, D.Sc., F.R.S.—The author showed that the mass of a molecule of hydrogen is a quantity of the same order as a decigramme divided by 10^{24}—*i.e.* a twenty-fourth decigrammet, which is the same as the twenty-fifth grammet. (The grammets are the decimal sub-divisions of the gramme, of which the first is the decigramme, the second the centigramme, &c.) The mass of the chemical atom of hydrogen may be taken to be half the twenty-fifth of the grammet. This value is based on the conclusion arrived at by several physicists—that the number of molecules in a cubic millimetre of a gas at ordinary temperature and pressure is somewhere about a unit eighteen (10^{18}), from which it can be shown that the number of molecules per litre must be about a unit twenty-four (10^{24}). From this, together with a knowledge of the weight of a litre of hydrogen, the above value for the mass of a molecule of hydrogen has been deduced. The mass of a molecule of hydrogen being known, it is possible now to determine approximately the masses of all other simple substances and of compounds also.

Prof. Osborne Reynolds then made a communication to the Section on the subject of *Dilatancy*, which was also read before Section A (see NATURE, vol. xxxii. p. 535).

On Physical Molecular Equivalents, by Prof. F. Guthrie, F.R.S.—The author pointed out that the *cryohydrates* are solid compounds of water and salts possessing very low melting-points, in which the mass ratios, whilst definite, are other than those of the ordinary chemical mass ratios. Another class of somewhat similar compounds has been discovered, which are quite analogous to the ordinary hydrates, and to these the name *sub cryohydrates* has been given. Metallic alloys are true homologues of the cryohydrates ; the ratios in which metals unite to form the alloy possessing the lowest melting-point are never atomic ratios, and when metals do unite in atomic ratios the alloy produced is never *eutectic, i.e.*, having a minimum solidifying point. Thus pure cast-iron is not a carbide of iron, but an *eutectic* alloy of carbon and iron. Similar hyperchemical mass ratios are found to exist amongst anhydrous salts ; when one salt fused *per se* acts as a solvent to another salt, forming *eutectic* salt alloys, similar to *eutectic* metallic alloys and the cryohydrates. The study of solution affords other instances of masses of unlike matter dealing critically with one another when not in any integral ratio of their molecular masses. Liquids, unsuspected of having chemical or physical relationships, are found, when mixed with one another, either to get warm and finally lose volume, or get cool and gain volume. In the first place chemical union is supposed to take place, and it appears certain that chloroform unites chemically with alcohol, ether with amylene, and benzene with ether, forming bodies analogous to the *sub-cryohydrates* and their prototype the *sub-cryohydrate* $C_2H_6O + 4H_2O$. The examination of those cases in which expansion and cooling results from admixture, shows that the maximum effects are produced when the admixture takes place in certain simple molecular weight ratios. This the author proposes to call the maximum molecular repulsion, which, in the case of carbon disulphide and chloroform, is attained with a mixture in which the molecular ratios are as 1 : 1. Mixtures in these proportions are found to show abnormally high vapour-tensions. And the author has made experiments which appear to show that, when carbonic acid and hydrogen are mixed, the joint volume is measurably greater than the sum.

On the Evidence Deducible from the Study of Salts, by Spencer Umfreville Pickering, M.A.—In this paper the author deals with the evidence as to the molecular weights of salts, derived from a study of the composition (1) of hydrated salts ; (2) of basic salts ; (3) of double salts. He also criticises the evidence deducible from experiments on hydration, dehydration, and the vapour tension of hydrated salts, and finally examines the conclusions drawn from the calorimetric investigations of such compounds. The conclusions arrived at by the author are that, although in a few isolated cases the molecular weights obtained would appear to be greater than the analytical results necessitate, still, in a vast majority of cases there are no grounds for multiplying these weights, and indeed there is a considerable mass of evidence in favour of adhering to the simplest possible formulæ. Such a conclusion may, at first sight, appear opposed to conclusions drawn from other sources. On the one hand the author considers it undeniable that if we succeed in determining the number of replaceable portions of the elements in any compound, we determine *ex hypothesi* the number of atoms in the molecule, that is, the molecular weight ; and whilst the data at our disposal at present are of the most meagre description, nevertheless are such as seem to point to the simplicity of these molecules. On the other hand, considerations based on the crystalline form and other physical properties of bodies force on us the conclusion that liquid and solid molecules are in all probability of a very complicated nature, certainly more complicated than gaseous molecules. Both these conclusions the author considers to be reconcileable with one another and contends that because the smallest particle of a substance which enters into a chemical reaction may be simple, there can be no reason why many of these particles may not agglomerate and act in unison as regards certain physical forces. That this agglomerate does not act as a unit towards chemical forces would simply imply that the force which unites the individuals constituting it is not chemical force, or is chemical force of such a weak nature that, in presence of the strong chemical agents we make use of, it is inappreciable. The molecule of a chemist is not necessarily identical with the molecule of the physicist.

On the Molecular Weights of Solids and Salts in Solution, by Prof. W. A. Tilden, D.Sc., F.R.S.—Accepting the conclusion that bodies in the solid state consist of units or molecules of a very complex character, and made up of a number of such smaller aggregates as compose the molecules of gases, the author is inclined to go further, and sees no reason for limiting the number of small molecules, which may thus be bound together to form a physical unit. From the law of Dulong and Petit, and of Neumann's law, it would appear that in solid elementary bodies, and in salts, &c., there is no difference between molecule and mass, and that the physical unit is the atom. The facts known concerning specific volumes and refraction equivalents support such a conclusion. According to this view solid bodies are composed of atoms, which are only distributed into molecules capable of independent existence ; when the body becomes a fluid. Such a view implies that chemical combination between atoms and the combination of molecules which ensues when a gas or liquid returns to the state of a solid are phenomena of the same nature, which agrees with the commonly recognised resemblance between the process of dissociation and those processes of fusion and evaporation. Another consequence of this view is that the idea of limited valency must be confined to gaseous substances. With regard to solutions, many facts are known, which indicate that the molecules of dissolved substances are smaller than those of solids. With regard to the question of water of crystallisation, the author does not altogether agree with the views of Dr. Nicol (see *Report on Solution*, NATURE, vol. xxxii. p. 529), but considers that the composition of the salt molecule in solution is dependent chiefly upon temperature, and in such a way that the dissolved molecule retains the same amount of water as the crystals formed at the same temperature. As the temperature rises these molecules undergo a gradual dissociation, and at a certain temperature the salt molecules lose this water and become anhydrous.

On the Molecular Constitution of a Solution of Cobaltous Chloride, by Prof. W. J. Russell, Ph.D., F.R.S.—A thin layer of cobaltous chloride gives an absorption spectrum consisting of two broad, ill-defined bands. If the chloride be mixed with potassium, sodium, or calcium chlorides, the spectrum of these mixtures, both in the solid and fused state, is different from that of cobaltous chloride, and consists essentially of four bands, two of which are marked and characteristic. This same spectrum is obtained with solutions of cobaltous chloride in absolute alcohol, in amyl alcohol, in hydrochloric acid, or in glacial acetic acid. This spectrum would, therefore, appear to be that of cobaltous chloride in an altered molecular state. The spectrum of an aqueous solution is again different, and consists of one broad band nearer to the blue end than the other bands, but the addition of cobaltous chloride to such a solution, or of such bodies as possess an affinity for water, causes a reversion of the spectrum to that of the anhydrous cobaltous chloride. Heat also produces the same effect, and it would appear from these results that the anhydrous chloride can exist in aqueous solutions. The changes in the character of the spectrum of an aqueous solution produced by heat may be explained as arising from a dissociation of some of the hydrates existing in the solution, and the production of anhydrous cobaltous chloride. Further, the fact that those solutions containing the anhydrous salt more readily transmit the blue rays and absorb the red rays, whilst those containing hydrates in solution more readity transmit the red rays, would indicate that the molecule of the hydrate is smaller than that of the anhydrous salt. The action of water on the anhydrous salt, therefore, is not to form an additive compound, but to split the molecule of the anhydrous salt and form one in which water replaces cobaltous chloride.

In the discussion which followed the reading of these papers Prof. Ramsay said that the density of a saturated vapour afforded a clue to the molecular complicity. Now while a liquid such as water or alcohol gave a saturated vapour, which at a sufficiently low temperature and corresponding low pressure had normal density, the saturated vapour of acetic acid, on the contrary, had an increasing density with fall of temperature, this density showing that the molecule has passed the stage $C_4H_8O_4$ and is on its way to $C_6H_{12}O_6$, if the results are to be explained by agglomeration of simple molecules at all.

Dr. Gladstone remarked that from the evidence of coloured salts in solution such as the sulphocyanides of cobalt, he believed that a dissolved salt might be in an anhydrous condition and might become more and more hydrated as the mass of water in its presence is increased or its temperature lowered. Evidence of other changes might also be obtained from the colour of solutions. He did not think that the refraction of light by a body is often likely to tell anything about its molecular volume; but in the case of the polymeric olefines, C_nH_{2n}, the specific refraction and dispersion will probably decrease considerably as the value of n becomes greater, on account of the increasing proportion o carbon in the normal condition.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following have been appointed examiners for the ensuing year:—Physics and Chemistry: Prof. Schuster, F.R.S., and Mr. R. T. Glazebrook, F.R.S.; Chemistry: Messrs. A. Scott and W. J. Sell; Mineralogy: Prof. Liveing; Geology: Messrs. J. J. H. Teall and J. E. Marr; Botany: Messrs. W. Gardiner and H. M. Ward; Human Anatomy: Profs. A. Macalister, F.R.S., and G. D. Thane; Comparative Anatomy: Mr. A. Sedgwick; Physiology: Prof. Michael Foster, Sec. R.S., and Mr. A. S. Lea; Pharmacy and Pharmaceutical Chemistry: Prof. Wyndham Dunstan.

Mr. F. H. Neville, Sidney Sussex College, is appointed as teacher of chemistry with reference to certificates for M.B.

In the late Higher Local Examinations the arithmetic and Euclid were fairly well done.

In Algebra and Trigonometry the cases of gross failure were fewer, while the work of the better candidates was not so good as last year.

Considerable care had been taken to apprehend the facts of Mechanics, but some candidates merely stated a result when asked to "prove" or "establish" it; and when asked to draw inferences by means of the laws of motion, they drew inferences from quite other considerations. A certain amount of knowledge of Descriptive Astronomy was shown by some of the candidates: two of the twenty-two obtained more than half marks.

Only four candidates took the paper in Differential and Integral Calculus. Two of them showed a sound knowledge of the early definitions and rules for differentiation; the other two (who alone attempted the last eight questions) were less successful on the whole, and had confused ideas on the elementary parts of the subject. No marks were obtained in Integral Calculus.

In the Elementary Natural Science paper the work was as a whole extremely poor, notably in Chemistry.

In Physics the candidates seemed to possess very little power of giving concise and definite answers. The attempts to describe experiments and experimental proofs of physical laws were remarkably weak, and might be described as a mere echo of experimental lectures only partially understood; they showed none of the results that might fairly be expected from a careful consideration of those facts and principles which were clearly within the candidates' reading.

In Physical Geography and Geology most of the papers were good, but none excellent.

In Physiology the answers were on the whole satisfactory, while three or four papers showed that the writers had gained a very creditable acquaintance with the subject.

In Zoology most of the papers were far from creditable, and exhibited but little real or intelligent knowledge. The answers to the practical questions were uniformly bad.

In Botany the candidates displayed but little knowledge of what is meant by the terms "growth," and "collateral," and no one gave a good description of the method of measuring growth. The plant given for description was fairly well described, but the floral diagram was in many cases imperfect. The germination of a seed was not well described. Several students described *Penicillium*, *Mucor*, and *Agaricus*, as parasites.

At Gonville and Caius College an examination will be held on December 8 for open scholarships and exhibitions. Natural Science candidates, who must be under nineteen years of age, will be examined in Physics, Chemistry, Biology, and Animal Physiology; proficiency will be expected in at least two of these subjects, of which chemistry must be one. Further information will be given by the tutors.

At the annual election on November 2 at St. John's College, the following were elected to Fellowships:—A. Harker, M.A., Eighth Wrangler 1882, First Class Nat. Sciences Tripos (Physics) 1883, Woodwardian Demonstrator in Geology; D. W. Samways, M.A. (D.Sc. London), First Class (with distinction in Physics) Nat. Sciences Tripos, 1881, University Extension Lectures in Physics and Physiology; W. H. Bennett, M.A. (M.A. London, Mathematics), First Class Theological Tripos 1882, Tyrwhitt Hebrew Scholar; W. Bateson, B.A., First Class Nat. Sciences Tripos (Zoology) 1883, Assistant Demonstrator of Animal Morphology; R. W. Hogg, B.A., Sixth Wrangler 1883, First Class, Part III., Mathematical Tripos, 1884.

THE annual election of Fellows of St. John's College, Cambridge, took place on Monday, when the five vacancies were filled up by the election of the following graduates of the College:—

(1) A. Harker, M.A., 8th Wrangler, 1882—First-class Natural Sciences Tripos, Part I., June, 1882, First-class Natural Sciences Tripos, Part II., June, 1883, for Physics, Woodwardian Demonstrator in Geology.

(2) D. W. Samways, M.A., D.Sc. London—First-class Natural Sciences Tripos, 1881, distinguished in Physics.

(3) W. H. Bennett, M.A.

(4) W. Bateson, B.A.—First-class Natural Sciences Tripos, Part I., June, 1882, and First-class Natural Sciences Tripos, Part II., June, 1883, for Zoology and Comparative Anatomy, Assistant Demonstrator in Animal Morphology.

(5) R. W. Hogg, B.A., 6th Wrangler, June, 1883, and in the first division Mathematical Tripos, Part III., January, 1884.

PRELIMINARY SCIENTIFIC EXAMINATION OF THE UNIVERSITY OF LONDON.—The following statistics of the Preliminary Scientific Examination for the degree in Medicine of the University of London are of importance as conclusively proving that those members of the medical profession who so urgently declare this examination to be too severe are entirely misinformed. At the examination in last July there passed from all parts of the United Kingdom 159 candidates. Nearly an equal number were rejected; but that this is owing to the fact that the candidates had not sought the usual and proper methods of preparation, and not to the fact that the examination is a specially difficult one, is proved by the following important facts:—63 candidates entered for this examination, stating that they had prepared for the examination wholly or in part at University College, London. Of these 63 candidates 52 passed, and several took honours. Thus less than one-fifth were rejected of those candidates who attended the carefully-organised teaching of University College. This is an exceedingly small proportion of failures for any pass examination. From other London colleges a much smaller number of successful candidates is recorded. The largest number after the University College list is that of St. Bartholomew's Medical School. Instead of 52 we fine here, however, 16. Then come Guy's, St. Thomas's, and King's College, each with 11, London Hospital with 5, St. Mary's with 3, and St. George's, Middlesex, and Charing Cross, each with 1. These figures lend strong support to the suggestion which has so often been made, that the Hospital schools would do well to cease the attempt to teach purely scientific subjects, and should recognise the Faculty of Science of University College as the common preliminary scientific school for all London hospitals. The students themselves, it is obvious, already take this view. Of the 52 successful candidates belonging to the Faculty of Science of University College only 12 have entered the Faculty of Medicine of that institution. The remaining 40 have selected their hospitals without prejudice. Several have obtained entrance scholarships at the large London hospitals.

SCIENTIFIC SERIALS

Bulletin de l'Académie Royale de Belgique, July.—Observations on the planets Jupiter and Venus, made at the Astronomic Institute of Ongrée, by M. L. de Ball.—On the eurites, or older rhyolithic formations of Grand-Manil, by M. Ch. de la Vallée Poussin.—On the pretended bacterian origin of diastase, by M. Emile Laurent.—On the organic structure and growth of *Phycomyces nitens*, by the same author.—On the Devonian limestones of coral origin and their distribution throughout the palæozoic formations of Belgium, by M. E. Dupont.—Theory of elliptic functions: Hermite's equation, by M. J. A. Martius da Silva.—The philosophic system of the Bhagavadgîta, by M. Le Roy.—An unpublished Latin inscription referring to T. Desticius Severus, Procurator of Gallia Belgica, by M. Bartolini.—Origin of the Flemish inhabitants of Belgium, with preliminary remarks on the Suevi of Flanders, by M. Alph. Wauters.

August.—Fresh researches on the apparent enlargement of the sun, moon, and stars at the horizon, by M. Paul Stroobant.—Reaction of the sulphate of barium and the carbonate of sodium under the influence of pressure, by M. W. Spring.—Note on the lower Devonian rocks of Belgium: the pudding system of Weris and its transformation, by M. E. Dupont.—Experimental researches on the sense of sight in insects: Do insects distinguish the outlines of objects? by M. F. Plateau.—Determination of an empirical relation connecting the tension of vapour with the coefficient of internal friction in fluids, by M. P. De Heen.—The eurites of Grand-Manil (continued), by M. Ch. de la Vallée Poussin.—Biographical notices of Mathieu de Morgues and Philippe Chifflet, by M. Auguste Castan.—On the old Persian, Hindu, and Chinese literatures, by M. Ch. de Harlez.—Note on the domain of the Aduaticæ, and on some other questions of ancient Belgian geography, by M. L. Vanderkindere.

Schriften der Physikalisch-Okonomischen Gesellschaft zu Königsberg i. Pr., 25th year (1884).—1st and 2nd parts.—Memorial address on Oswald Heer (with list of works) by A. Jentzsch.—On the development of the oil-vessels in the fruits of Umbelliferæ, by J. Lange.—Festival address on the centenary of Bessel's birth, by I. Franz.—Correction of Sanio's memoir on the numerical relations of the flora of Prussia, by J. Abromeit.—Reports on local botany, museum collections, &c.

SOCIETIES AND ACADEMIES

London

Mineralogical Society, October 20.—The Rev. Prof. Bonney, President, in the chair.—Messrs. F. R. W. Daw, John Daw, Jun., G. F. Kung, and C. C. Ross, M.P., were elected members. The following were elected officers and Council for the ensuing year:—President: L. Fletcher, F.G.S.; Vice-Presidents: Rev. S. Haughton, F.R.S., Rev. Prof. T. G. Bonney, F.R.S.; Council: C. A. Burghardt, LL.D., A. Geikie, F.R.S., Rev. H. Gurney, M.A., Hugo Müller, F.R.S., Rev. W. W. Peyton; Treasurer: R. P. Greg, F.G.S.; General Secretary: R. H. Scott, F.R.S.; Foreign Secretary: T. Davies, F.G.S.; Auditors: B. Kitto, F.G.S., F. W. Rudler, F.G.S. The Secretary read the following Report of Council:—The balance-sheet for the year 1884, which appeared in No. 28 of the *Journal*, showed that the finances of the Society were in a healthy condition, the excess of assets over liabilities amounting to 215*l*. 12*s*. 4*d*. The number of Members and Associates elected during the year has been seven, and the number of resignations five, while the names of four Members and one Associate have been removed from the list for non-payment of subscriptions for three years. The Council regret that they have to report also the death of Alexander Murray, C.M.G., of St. John's, Newfoundland. Three meetings have taken place since the last anniversary: those in December and March were held in the Museum of Economic Geology, by kind permission of the Director-General of the Survey; the third was held in Glasgow in the month of June, in the rooms of the Philosophical Society. This, the second Scottish meeting, was, like its predecessor in 1884, a decided success. Three parts of the *Journal* have been issued during the year. Among their contents the Council would especially draw attention to Mr. Miers' contributions, including his careful index to the mineralogical literature of the year. Herr Sjögren's paper on graphite also deserves notice; it is a translation from the Swedish, as it originally appeared in the *Forhandlingar* of the Stockholm Academy. In conclusion the Council would only remind the members that it is very desirable that they should co-operate actively in the working of the Society by the contribution of papers to be read at its meetings and published in its *Journal*. It is by such co-operation alone that the Society can be maintained in a state of vigorous activity. The President then delivered his address, which will appear in the *Journal*. Prof. Bonney then vacated the chair, which was taken by the newly-elected President, Mr. Fletcher, and the following papers were read:—H. A. Miers, on a crystal of orthoclase.—R. H. Solly, notes from the Mineralogical Laboratory, Cambridge, being an account of the following minerals:—garnet, axinite, asbestus, and semiopal from the Mid-Devon Copper Mine, apatite or Francolite from the Levant Mine, and Fluor Spar from Holmbush.—Dr. Max Schuster, results of the crystallographic study of danburite.—W. E. Dawson, analysis of a supposed new chromate of lead from the Transvaal.—Prof. Lewis exhibited a fine crystal of colemanite; and Mr. Fletcher exhibited some Roman coins found near Chester and presenting crystals of cuprite.

Sydney

Linnean Society of New South Wales, August 26.—Prof. W. J. Stephens, M.A., F.G.S., President, in the chair.—The following papers were read:—List of plants in use by the natives of the Maclay Coast, New Guinea, by N. de Miklouho-Maclay, with botanical remarks by Baron Ferd. von Müller, K.C.M.G., &c. Baron Maclay in this paper gives (1) a list of the plants used as food, dividing them into those cultivated and those growing wild; (2) those cultivated as stimulants or for medicine; (3) those useful in various ways for household purposes; and (4) those introduced since 1871. An Appendix by Baron Müller gives an account of some of the plants mentioned by Baron Maclay and gives a description of a new species named *Bassia maclayana*.—Catalogue of the Coleoptera of Australia, by George Masters. This is the first of a series of papers intended by Mr. Masters to make a complete and perfect list of all the known species of Coleoptera in Australia. The present part comprises the Cicindelidæ and Carabidæ, and numbers 950 species.—Descriptions of three new Port Jackson fishes, by J. Douglas-Ogilby, Assistant Zoologist, Australian Museum. The three species here described are *Scyllium anale*, *Heliastes immaculatus*, and *Pempheris lineatus*.—Mr. Macleay exhibited a section of a branch of an orange tree completely perforated by the larva of a longicorn beetle. Also three specimens of a beetle found in the perforated wood. The exhibit had been sent by Mr. M. de Meyrick, a member of the Society, who stated that many orange trees had suffered in the same way in the neighbourhood of Penrith. Mr. Macleay said the injury was caused by the larva of *Monohammus fistulator*, a grub destructive to all kinds of fruit trees, but, as far as his experience went, its ravages were confined to old or decaying trees, and it would be interesting to know if in any instance it had been found to attack young and vigorous plants. The accompanying beetles were heteromerous insects of the genus *Amarygmus*, and were not in any way the cause of the injury to the tree.—Mr. A. Sidney Olliff exhibited specimens and sketches of *Cryptommatus jansoni*, Matt., a curious beetle which was found under the fur of the common rat in Tasmania, and said that he believed new and interesting species with similar habits might be found in Australia if the smaller mammals were examined when freshly killed. Two allied species were known from Peru, one of which was found in the fur, and also in the nests, of mice. The specimens exhibited were captured by Mr. A. Simson and had been obtained from Mr. Morton, of the Hobart Museum.

PARIS

Academy of Sciences, October 26.—M. Bouley, President, in the chair.—A means of preventing rabies from the bite of a mad dog, by M. L. Pasteur. After almost endless experiments the author announces that he has at last succeeded in obtaining a practical and prompt prophylactic remedy, which has already proved sufficiently efficacious in the case of dogs, to justify the belief in its general efficacy when applied to all animals, including man himself. A full account of the process will be found at p. 1 of this week's NATURE.—Direct fixation of free atmospheric nitrogen in plants through the agency of certain argillaceous clays, by M. Berthelot. Some years ago the author found that to atmospheric electricity was largely due the attraction of free nitrogen to the immediate elements of vegetable organisms. After fresh experiments conducted for two years at the Meudon station for vegetable chemistry, he has now discovered a new and perhaps a more general cause of this arrestation in the silent but incessant action of argillaceous clays and of the microscopic organisms contained in them. In this memoir he gives the results of over 500 analyses of four different clays constituting five distinct but simultaneous series of experiments in a closed chamber, in a field under shelter, on top of a tower 28 metres high without shelter, in hermetically sealed flasks, and lastly in soil artificially sterilised.—Note on the Cynthiadæ of the French seaboard, by MM. H. de Lacaze-Duthiers and Yves Delages. In the present paper the authors restrict their remarks to the typical *Cynthia morus*, a characteristic group of simple ascidians occurring in the English Channel, in the Atlantic, and in the Mediterranean. The several varieties are determined and the anatomy of the whole group described in detail.—Note respecting some recent communications on waterspouts, by M. Faye. The author's remarks refer to the report issued by the United States Army Signal Service on the thirteen tornadoes of May 29–30, 1879, the most complete and elaborate account of these phenomena hitherto published.—Experiments on the transmission of force by electricity between Paris and Creil, by M. Marcel Deprez. These costly experiments, begun on October 17, 1884, and carried out with the aid of MM. Rothschild, have so far proved very satisfactory. In a future communication complete tables are promised of all the electric and mechanical data of the experiments hitherto made both by the author and by M. Collignon.—On the propagation of motion in bodies, and especially in perfect gases, by M. Hugoniot.—Note on a new process for making hydrogen gas, by MM. Felix Hembert and Henry. By this simple and economic process hydrogen gas available for numerous combinations applicable to the arts and industries may be produced at the rate of 0·015 franc the cubic metre.—Discovery of a new planet (No. 25*a*, of 13th magnitude) at the Observatory of Nice, by M. Perrotin.—Remarks on the new star in the nebula of Andromeda, one illustration, by M. E. L. Trouvelot. This new star A, as well as the already discovered B, would appear to form part not of the nebula itself, but of the Milky Way. — Application of M. Lœwy's new methods for determining the absolute co-ordinates of the circumpolar stars, without the necessity of ascertaining the instrumental constants (polar distances), by M. Henri Renan.—Questions relating to a bundle of plane cubic figures (continued), by M. P. H. Shoute.—On birational plane geometrical transformations, by Mr. G. B. Guccia.—General differential equations reducible to quadratures, by M. Wladimir Maximowitch.—Note on a new absorption spectroscope, by M. Maurice de Thierry. This apparatus enables the observer to study fluids under a thickness of 3 to 10 metres, and to detect the presence of oxyhemoglobine in a liquid containing not more than 1-5,000,000th of that substance. It is an instrument of extreme precision, capable of rendering great services to forensic medicine, physics, and biological chemistry, by facilitating the study of the absorption spectra of fluids examined under a great thickness.—Note on a new neutral carbonate of magnesia, by M. R. Engel. This is an anhydrous carbonate absolutely different both from the natural neutral carbonate (CO_3Mg) and from the crystallised and anhydrous neutral carbonate artificially obtained by M. de Senarmont.—On the volatile property of the mixed organic compounds, by M. Louis Henry.—Note on the zymotic properties of four kinds of virus: those of the spleen, of puerperal septicemia, of gangrenous septicemia, and of the symptomatic charbon of the ox, by M. S. Arloing.—On the existence of two kinds of sensibility to light—the sense of colour and of form, by M. H. Parniaud.—On the physiological action of the sodic sulpho-conjugate of rocellic acid, by MM. P. Cazeneuve and R. Lépine.—On the circulation of the blood in the nerve-cells of the intervertebral ganglia, by M. A. Adamkiewicz.—On the method of distribution of certain sympathetic intra-cranial chords, and on the existence of a sympathetic root of the ciliary ganglion in the goose, by M. F. Rochas.—On the development of the nematodes (second note), by M. THE INTERNATIONAL SANITARY CONFERENCE OF ROME, 1885

THE first volume of the Proceedings of the International Sanitary Conference of Rome has been issued just at the time when the question of the re-assembling of the Conference is a matter of diplomatic discussion. The Roman Conference of this year was brought together by the Italian Government because it was felt that, after the cholera experience of 1883 in Egypt and of 1884 in Southern Europe, advance might be made in determining the bases of an International Code as to quarantine or other preventive measures. The previous Conference had been held at Vienna in 1874, and the conclusions then arrived at had indicated substantial progress since the preceding meeting at Constantinople in 1866. Under these circumstances nearly all civilised Governments responded to the appeal of Italy, and five delegates were deputed to represent this country. Two of these, Sir W. Guyer Hunter and Dr. Thorne Thorne, acted with the British Ambassador at Rome for Great Britain, and Sir Joseph Fayrer with Dr. Timothy Lewis went as representatives of our Indian Empire. Soon after the opening proceedings, a Technical Commission, consisting of the medical delegates, was formed, and it is essentially with the proceedings of that Commission that the volume referred to has to do.

With the ready assent of Dr. Koch, the Commission decided at the onset not to discuss scientific questions bearing upon etiology or otherwise, and the series of resolutions arrived at deal almost exclusively with the measures which are deemed necessary to prevent the spread of cholera in Europe. Perusal of the proceedings at once shows that the Powers bordering on the Mediterranean had one principal object in view. They were convinced that shipping passing from India *viâ* the Suez Canal constituted the great source of danger to ports on the basin of the Mediterranean; they knew that the sanitary state of the majority of those ports could not withstand the importation of infection; hence, cost what it might to other nations, they were determined to place restrictions upon shipping passing through the canal. It is true that the utter failure of quarantine measures had once more been abundantly shown during the 1884 epidemic, and for this reason the Commission decided to drop the word quarantine altogether; and they proposed, instead of the ten days' quarantine which had been sanctioned at Vienna, to require a detention of five days for the purposes of "observation." But, as was pointed out by the English delegates, this was quarantine pure and simple, for it involved the disembarkation of all on board vessels which might be regarded as infected by some internationally appointed officer, and the detention of men, women, and children in the filthy lazarets of the Red Sea shores for as many consecutive periods of five days as the officer in question might choose to dictate, so long as he could regard any one amongst the persons thus isolated as having suffered from symptoms which in his opinion resembled cholera. As regards European protection, it was also contended that such a measure was unnecessary in the case of British ships, and the Commission were twice challenged to give a single instance in which cholera had been brought into the continent of Europe by means of a British ship coming from India. And if it was unnecessary, it was contended that, provided British ships touched at no ports on their way home, they should be allowed the free passage of the Suez Canal as of an ordinary arm of the sea.

But quarantine restrictions were not only held to be unnecessary, they were also shown to be distinctly mischievous in so far as they led the inhabitants of threatened countries to rely on Government measures of that description instead of adopting measures of sanitation which constituted the true remedy against cholera spread. And here the experience of England was shown to be strikingly opposed to quarantine. It is now some ten years since England, adopting one of the alternative measures sanctioned at Vienna, decided that since quarantine must always fail, the country would place its trust in an inspection of in-coming vessels, together with the immediate isolation of the sick in hospital, and in securing such improvement in the sanitary state of the country as would tend to remove the conditions favourable to the diffusion of cholera if imported. And Dr. Thorne Thorne, whilst pointing out in detail that during that period of ten years our sanitary authorities had spent some 27,250,000*l.* in large public health works and that this had in truth been a remunerative expenditure by reason of the saving of life which had followed it, asked what country had shown a greater proof of the value it set on human life than England had, and contended that it would be an unfortunate day if we were to replace such a system by the imposition of a five days' quarantine. Indian statistics proving similar results were also brought forward by Sir Joseph Fayrer, and they must be regarded as unanswerable.

In short, the English delegates contended that we must look, above all, to improved sanitation in order to get rid of the danger of cholera; that countries which are taught to rely on the false security of quarantine measures and sanitary cordons will not at the same time spend their money on sanitation; and that the very countries which had fitted themselves to resist cholera by making real and substantial progress as regards sanitary improvements, and had thus effected a saving in life from infectious diseases, were those which had determined to place little or no trust in measures of quarantine.

Compared with the resolutions of the Vienna Conference, the conclusions arrived at in Rome do in many respects admittedly afford evidence of considerable advance, but they are vitiated by the initial error of trusting to modified quarantine restrictions, instead of boldly facing the need for improved sanitation. As yet these conclusions are those of the Technical Commission only, and it remains to be seen whether, since the English delegates are opposed to their colleagues on a matter of such vital principle, any object will be gained by the re-assembling of the Plenary Conference, to discuss the recommendations made by the Commission.

"EVOLUTION WITHOUT NATURAL SELECTION"

Evolution without Natural Selection; or, The Segregation of Species without the Aid of the Darwinian Hypothesis. By Charles Dixon. (London: R. H. Porter, 1885.)

THE title of this little book is misleading. Far from offering any account of evolution without natural selection, the author habitually ascribes to natural selection the lion's share of the work, only reserving a few odds and ends of small detail as results ascribed by him to other agencies. Such odds and ends have reference almost exclusively to minute differences of coloration in allied species of birds—the argument being that these differences are too minute to count for anything in the struggle for existence, and therefore cannot have been due to survival of the fittest. Now, although Mr. Dixon has presented in a brief and very readable form a considerable number of most interesting facts upon this head, they cannot be said to have any bearing upon the Darwinian hypothesis. For even if it were conceded, for the sake of argument, that all the cases given of slight variation in allied species are without utilitarian significance (although this would be a large concession), we should still be well within the four corners of Darwinism. It is the very essence of the Darwinian hypothesis that it only seeks to explain the apparently purposive variations, or variations of an adaptive kind; and, therefore, if any variations are taken to be non-adaptive, *ex hypothesi* they cannot have been due to natural selection. But as such variations are, even upon the showing of our author himself, for the most part rare and always trivial, they may be freely presented to the anti-Darwinians without any loss to Darwinism. Indeed, Mr. Darwin himself has clearly recognised the occurrence of such trivial specific characters, and observes that if they are "really of no considerable importance in the struggle for life, they could not be modified or formed through natural selection." But it is no part of the theory of natural selection that it should necessarily occupy the whole field of possible causation in the genesis of species. It is surely enough if it be taken to explain all cases of *adaptation;* and this, if we understand him aright, Mr. Dixon is prepared to allow. Thus, for example, he says:—"We can therefore understand how the modifications which many species have undergone, through climatic and other causes, have been taken advantage of *when they began to be of service;* although at the time the modifications took place they were not of the slightest use!" The note of admiration here seems to imply, in accordance with the whole tone of his book, that the writer considers this view to be in some way an important emendation of Darwinism. But, in point of fact, it is Darwinism pure and simple. For Darwin is most express in affirming that natural selection cannot be supposed the original cause of variation, being only called into play when the variations, as Mr. Dixon says, begin to be of service. What these original causes of variation may be is a distinct question, and one which it remains for the future to answer. For, as we shall immediately proceed to show, Mr. Dixon has not been successful in furthering the solution.

The influence on which he chiefly relies is that of isolation, and he has gathered a number of interesting facts whereby to justify his opinion. It is needless to say that this opinion also is quite in harmony with Darwinian teaching; for when a section of a species is geographically isolated, the constituent members of it are virtually confined to a world of their own whereon to begin a new course of history, and being thus cut off from interbreeding with the main stock, there is nothing remarkable in the fact that, under such circumstances and in some cases, the history of the isolated section should not run perfectly parallel with that of the main stock. This, indeed, is Mr. Dixon's own view, and we should have no criticism to offer upon it, if, on the one hand, he did not present it as anti-Darwinian, and if on the other hand he had been more clear in distinguishing between a condition and a cause. He everywhere speaks of isolation as the cause of minute specific characters; whereas it is obvious that at best it can only be the condition to the operation of causes, the nature of which it apparently does not occur to him to suggest.

Another agency invoked by the writer as a direct cause of variation is climate. But here again his views cannot be said to be anti-Darwinian, save in so far as they appear to err on the side of exaggeration. For even Mr. Spencer—who, by the way, ought to have been mentioned by Mr. Dixon as having long ago argued in favour of such direct causes of variation—would scarcely go so far as to attribute to climatic influences variations of a protective kind. This, however, is done by Mr. Dixon; but he maintains a judicious silence upon the closely-allied topic of mimicry. Yet such remarks as the following apply with even more force to the facts of mimicry than to those of protection:—"If the colour was donned from protective motives, to escape some special enemy, it seems impossible not to believe that the species would have become exterminated long before the protective colour reached a beneficial degree of development." Does Mr. Dixon believe that the exquisite details of form and colour whereby an insect is made to resemble a leaf can reasonably be ascribed to climatic influences? If not, what becomes of his argument touching the much less remarkable cases of protective colouring?

There still remains one other criticism of a general kind which it seems impossible to avoid making. On p. 7 it is said: "Natural Selection is probably the most potent agent in the evolution of new species only at such times when the earth is undergoing violent changes. . . . We can conceive how, as soon as violent changes once more pervade the world, the struggle for life will be infinitely greater than it is now. Then species will be matched against species, race against parent form, or race against race; all Nature will be thrown into a kind of chaos; and then Natural Selection will adjust the disordered balance," &c., &c.

Now, this passage, which appears to be intended as conciliatory to Darwinism, is the only really anti-Darwinian passage in the essay. For not only are the views expressed by it in direct contradiction to the now universally-accepted teaching of uniformitarianism, but they equally run counter to the emphatic contention of Darwin, that the great merit of his theory consists in its agreement with that teaching. Not in chaos or in cataclysm is the influence of natural selection to be sought, but in forest and in field, in river, lake, and sea, where all may seem most orderly and eloquent of peace.

But although we are thus unable to commend Mr. Dixon's philosophical views on topics connected with natural history, we should be sorry to take leave of his work without explicitly stating what has already been implied—namely, that his facts are better than his theories. On this account we consider that his essay well repays perusal, and therefore recommend it to the notice of zoologists. GEORGE J. ROMANES

FORESTRY IN POLAND

Forests and Forestry in Poland, Lithuania, the Ukraine, and the Baltic Provinces of Russia. With Notices of the Export of Timber from Memel, Dantzig, and Riga. Compiled by John Croumbie Brown, LL.D., &c. (Edinburgh; Oliver and Boyd. London: Simpkin, Marshall, and Co., and William Rider and Son, 1885.)

THIS is another contribution of Dr. Brown's to the subject of forestry and to the furtherance of the formation of the Museum and School of Forestry in Edinburgh, which, it was thought, might be the outcome of the Forestry Exhibition held in the Scotch capital last year. The consideration of the establishment of a forest school has since occupied a wider range of thought, consequent upon the action of Sir John Lubbock in the House of Commons, and in connection with this Dr. Brown's latest volume will probably be of some interest in showing what is effected in forest matters in countries somewhat beyond the track of the ordinary English traveller, notwithstanding that Dr. Brown has given us similar books to the present on the forests of Norway, Northern Russia, the Ural Mountains, &c.

The present book commences with a very readable comparison of the facilities of travelling in Poland, Lithuania, Courland, Estonia, and Livonia some forty years since and at the present time.

In the first chapter the character of the country along the railway for some 200 miles from St. Petersburg towards Poland is described as a dead level of marshes and bogs; such dry land as there is being to some extent covered with trees probably of no great age, "apparently," Dr. Brown says, "the scraggy representatives of extensive forests of a former day." Nowhere are such forests as may be seen in travelling in the Governments of Olonetz and Archangel in Northern Russia, and of Moscow, Orel, and others in Central Russia.

Entering Poland at Kovna, about 200 miles from Dunsburg, and advancing through the eastern portion of that country, Dr. Brown says the traveller remarks that agriculture appears to be carried on with a more scientific character than in the lands through which he has been passing. Agriculture seems also to be more remunerative; the crops are thicker. The fields are sown with wheat, whereas to the north of Kovna barley, oats, and flax alone are cultivated. All the more valuable cereals seem to flourish in Poland, and in passing through this district there is produced an impression that the soil is more productive than it is further to the north; that the climate must be more equable; and the superficial aspect of the land being more undulating, and at the same time more thickly wooded; that as an agricultural district it must be at least 50 per cent. superior to the Governments of St. Petersburg and of Pskoff. In Poland both wheat and wool are raised for exportation. Large crops of potatoes are grown for the production of spirits by distillation, and beetroot for the manufacture of sugar; and wood for building purposes is exported largely. The Scotch fir (*Pinus sylvestris*) and the oak (*Quercus Robur*) are of very superior quality.

The trees in this district are described as being different in character from those of the region traversed in coming hither. In the earlier stages of the journey they consisted almost exclusively of firs, birches, and willows, while around Berdicheff in Poland the woods are composed in a great measure of oaks, elms, and chestnuts.

Dr. Brown's second chapter is devoted to forest exploitation, and the third chapter to the important subjects of area, distribution, management, and produce of forests. The information under these heads is, however, to some extent technical and statistical. Some interesting facts are quoted regarding what may be called bye-products of the forest, such, for instance, as honey, which is collected by the bees largely from the flowers of the lime-tree, as well as from the thyme, hyssop, and buckwheat.

Regarding the schools of forestry in Poland, the most important arrangements for the study of forest science and economy by forest officials are at Novoi-Alexandria. Of these arrangements details are given, from which it seems that the institute is ranked as a college of the first class with two sections—one devoted to the study of rural economy and agriculture, the other to the study of forest science and forestry, with a farm, forest, and an extensive domain attached to it, the whole being placed under the Minister of Public Instruction at Warsaw. The staff of officials includes a director, inspector, five professors, eight tutors and three teachers, a laboratory superintendent, a mechanic, foreman of the workshop, land steward or manager of the estate, gardener and assistant, surgeon, secretary, book-keeper, and a superintendent of buildings. No professor can hold two chairs, and any of them after twenty-five years may be again and again reappointed for successive terms of five years each. A Board of Management, consisting of the director, inspector, and two professors, has the charge of expenditure to the amount of 300 roubles, to be sanctioned by the director; the expenditure of sums between 1000 and 5000 roubles requires the sanction of the Council; and the expenditure of sums above this amount that of the Ministry. The course of instruction embraces a very wide range of subjects. The instruction is given in the Russian language. Each professor and tutor is required to give six lectures a week, and teachers to spend twelve hours a week in class duties.

In the second part of Dr. Brown's book, which is devoted to Lithuania, the chapters are apportioned to considerations of the people, the aspects of the country, forests of the Dnieper, while Parts III., IV., and V. are respectively given up to the Ukraine, the timber exports of the Baltic, and the Baltic provinces of Russia.

OUR BOOK SHELF

Elementary Mechanics. By O. J. Lodge. (London and Edinburgh: Chambers, 1885.)

THIS is a revised edition of Prof. Lodge's Text-Book:—not much altered, so far as we can see even by the help of the rapid yet searching stereoscopic squinting, from the former edition. Why a writer, who begins by acknowledging his indebtedness to the really scientific works of Thomson and Tait, Clerk-Maxwell, and Clifford, should make frequent references to the merely "popular" and singularly loose *brochures* of Deschanel and Ganot, is a question more easily asked than answered. But it is totally unintelligible to us that, having begun with classical works, he should proceed to "recommend real students to read one or other" of these poor compilations. Was it not Horace Smith who said:—

> "Is there such scanty store of standard works,
> That students must be fed on foreign trash?"

But Prof. Lodge's own standard is far above that of the books to which he, unfortunately and unaccountably, refers his "real students." His work is a curious one. There is scarcely a trace of the dogmatism which is asserted to be so natural to the *genus* Professor! The author seems to place himself on the same level with his reader, and anxiously to seek for confirmation of his own statements in the assent of his pupils. This is, to say the least, unusual; but we cannot at once either commend, or find fault with, it. It is a new departure, and its value and usefulness must be judged by its success.

There are a few elementary, but important, points in Dynamics, by his treatment of which every author on the subject shows at once whether he is "sound in the faith" or not. On the whole, Prof. Lodge passes these tests with credit; and the rest of his book is of a much higher order than the run of elementary treatises.

There are, however, here and there some singular slips, which should be corrected in future editions. We note only one or two, but even these are destructive of the character for definiteness and accuracy which should be the leading feature of every scientific book. Thus, in §5 (where, unfortunately, a "statical" definition of force is introduced as well as a "kinetic" one) we are told that *change of motion* "is called" *Acceleration;* though in later sections the true meaning:—i.e. *Rate of* Change of *Velocity*:—is assigned to Acceleration. To the mere popular reader this may appear hypercriticism; but science is most careful to distinguish not only between *Change* and *Rate of Change*, but also between *Motion* and *Velocity*. Again, in § 16, serious confusion is introduced by the statement that the velocity of a point at unit distance from an axis "*is called*" the angular velocity of the rotating body. Prof. Lodge knows perfectly well that it is not so, and that none but unscientific people could confound a quantity of dimensions $[T^{-1}]$ with another of dimensions $[LT^{-1}]$; even when, as in the present case, their *numerical* values happen to be equal. We are tempted to seek an explanation of, and thus to find an excuse for, these and other similar slips, in his inexcusable partiality for the works of Deschanel and Ganot.

P. G. T.

The Ocean, &c. By W. L. Jordan. Second Edition. (London: Longmans, 1885.)

OF this elaborate work it is enough to say that it is based on "*The* New Principles of Natural Philosophy." These principles we sketched (June 21, 1883) in an article which, as his mode of acknowledgment showed, was by no means satisfactory to our Author. That *Vis Inertiæ* was entirely misunderstood by Newton, and that *unresisted* motion ultimately comes to rest, are among the chief foundations of this work! That a terrestrial globe whose frame is carried round through a portion of a curve, and then suddenly stopped, will rotate in consequence, is conceivable: but we should try to explain the fact by bad centering, or some such cause; certainly not by the assumption that, during the curvilinear motion, one part of the equator had necessarily a greater *linear* velocity than the opposite part. Our Author does not seem to be acquainted with the most elementary properties of the kind of motion called Translation! But this is merely, on his part, the most recent revival of Jelinger Symonsism:—for it assumes the fundamental tenet of that peculiar heresy; viz. that a body, which revolves round a centre, is not rotating if it turn always the same side to the centre. It is needless to say more on this melancholy waste of time, trouble, and ready money (the latter especially): on the part of an author who has been complimented by a reviewer of one of his other works as having "a familiar acquaintance with questions of finance." See *Advertisement* appended to the present volume.

P. G. T.

Spectrum Analysis. By Dr. H. Schellen. Translated from the Third German Edition by Jane and Caroline Lassell. Edited, with Notes, by Capt. Abney, R.E., F.R.S. (London: Longmans, 1885.)

THIS is the second edition of a well known book: in its general arrangement there is little departure from the first, which appeared in 1872. While the German edition from which it has been translated was being prepared, the author unfortunately died; it is not to be wondered at therefore that the present reprint does not reflect the present state of our knowledge so accurately as did the former one; indeed there is evidence that the German editor has been compelled by the sad circumstances under which this task devolved upon him to take what was readiest to his hand.

Some of the material however is very valuable: thus, for instance, we have a complete and well illustrated account of Vogel and Huggins' work on the spectra of stars, much interesting information concerning Prof. Rowland's new concave gratings; while the English editor has added a full account of Abney, Festing, and Langley's work on infra-red spectra, and Abney and Schuster's discussion on the photographs taken during the eclipse of 1882. With these exceptions the English, French, or Italian work accomplished during the last ten years is but imperfectly referred to. The names of Thollon and Tacchini, to say nothing of Crookes and Hartley, not even being in the index. To the student therefore the book is worse than useless, it is misleading. The popular reader, however, who does not care too much for completeness will find much information conveyed in a pleasant form. The main branches of the science, both in its terrestrial and celestial applications, are dealt with, and the methods of work are given. Great interest also attaches to the various forms of instruments used in the new science; many of these are described, from a new form of pocket spectroscope—which we learn from the index was devised by Capt. Abney—to the more complex apparatus designed by Vogel, von Konkoly, and others.

The theoretical parts are perhaps most to be avoided. The chapter on the plurality of spectra, for instance, will help the reader very little in coming to a conclusion upon a subject of fundamental importance. Such a statement, too, as that on p. 268, "That Kirchhoff's theory has received full confirmation from the observations of solar total eclipses" is not so true as the writer evidently thought it to be.

Again, on the question of the change of refrangibility of light due to the motion of a light source towards or from the eye. The complete statement made by Fizeau in 1848 appears to be unknown to the author, who attributes the solution of the problem to Mach, of Prague, in the year 1860.

The translators have done their work throughout in a very admirable manner, showing that they possess a perfect acquaintance with the subject.

There are, however, a few minor blunders; thus, for instance, the substitution of the word "length" for "longitude" in connection with the perihelion and node, plays havoc with the elements of a comet's orbit, given on p. 584, while the diagram on p. 387, illustrating the change of wave-length, is rendered unintelligible by the misplacement of the figures indicating miles per second.

A Practical Arithmetic on an entirely New Method. By John Jackson. (London: Blackie, 1885.)
Principles of Arithmetic. By Homersham Cox, M.A. (Cambridge: Deighton, 1885.)

As the title-pages indicate, these attack the subject from quite different sides: the former is eminently practical, and everything unpractical is carefully eschewed: the latter goes into the principles and considers all from the theoretic side, giving very little practice.

Mr. Jackson aims at giving the easiest and shortest rules he can; explanations are few, the deficiency to be met by black-board illustration. The fractional form for the solution of questions is adopted in the advanced rules; but the most noticeable feature is the exclusion of the rule of "subtraction" and the substitution of what the writer calls "incremental or complementary addition." To take an example in compound complementary addition:—A pays a bill of 15*s.* 8¾*d.* with a sovereign; the tradesman says, "15*s.* 8¾*d.* with a farthing (puts it down) make 15*s.* 9*d.*, and 3*d.* (puts it down) make 16*s.*, and 4*s.* (puts it down) make one pound." There is no new difficulty introduced here, and a beginner is taught a good practical lesson. There is a vast collection of examples, numerous examination papers, and a good store of sums worked out on the usual plan, as well as on that put forward by the writer. There are 25 pages of tables containing specific gravities, a mariner's compass, a perpetual calendar (to A.D. 1925), compound interest results, square and cube numbers, prime numbers and logarithms. Some space, as might be expected, is devoted to "mental arithmetic." We have shown, we think, that this book well merits its title of a "practical" arithmetic.

Mr. Cox at once states "the object is to give an account of the principles of arithmetic, omitting all merely mercantile applications." The author takes as his guide, in the main, Cantor's "Geschichte der Mathematik," consulting also Hankel and Nesselmann ("Algebra der Griechen"); but "the conception of the subject as a whole, and many of the details, have been taken from the mathematical portions of the works of Auguste Comte, and in especial from his last great work, the 'Synthèse subjective.'"

There is no index nor table of contents, which is a drawback to the ready use of the book. There is an introduction, and then come seven chapters. Chapter I. discusses Numeration; Chapter II. is devoted to the first four rules in four sections; Chapter III., on Properties of Numbers, is divided into four sections: (1) Theorems (the commutative, the associative, and distributive); (2) G.C.M.; (3) Prime and Composite Numbers; (4) L.C.M. Chapter IV., in four sections, treats of the four rules for fractions, and in the fifth section discusses Ratio and Proportion. Chapter V., in six sections, treats of Decimal fractions. Chapter VI., in four sections, discusses powers and roots, with geometrical illustrations and resumes (in Section IV.) the subject of Ratio and Proportion (applied to incommensurable quantities). Chapter VII., in three sections, resumes the discussion of Properties of Numbers, as regards Permutations, the Arithmetical and Geometrical Progressions, and Figurate Numbers. There are a few exercises appended to the sections. The book in parts reminds us much of De Morgan's Arithmetic: it will be valuable for teachers, even if they have read the works cited in Mr. Cox's preface. It is by no means a school-book, though senior boys may derive much interest as well as profit from its perusal.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*
[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Recent Total Eclipse of the Sun

By last mail I sent you a brief account of my eclipse observations at Tahoraite on the 9th inst., and a diagram illustrating the corona. Owing to a miscalculation as to closing time of mail the account had to be very hurriedly written; there was no time to revise it or to find out the longitude and latitude of the point of observation, but this information I am now able to supply from the Trigonometrical Survey Records at Napier:—

	Longitude		Latitude
Centre of railway station at Tahoraite, Hawkesbay	176° 5′ 7″·07	...	40° 13′ 17″·22

The longitude and latitude of the nearest Trigonometrical Station, No. 83, from which the above were calculated, seems to have been originally fixed with reference to Trigonometrical Station No. 60, Lighthouse Reserve, Napier, whose latitude then, according to observations taken in January 1871, was 39° 28′ 47″·30. According to fresh observations taken in February 1885 the latitude of the same point is 39° 28′ 43″·52 ± 0° 0′ 0″·04. If both series of observations are correct, a *reduction* in latitude to the extent of about 3″·78 must have taken place since 1871.

Considering the position of New Zealand at the Antipodes of Europe, where a reduction of latitude seems to have occurred, a reduction like the one above indicated, bearing as it does on a very interesting question, has particular importance and urgently calls for confirmation. As mentioned in my last letter, the corona reminded me of an auroral display. The rays all seemed radially disposed and perfectly straight with well defined edges. The differences in length were very remarkable. All the observers I have spoken to agree as to the position of the longest ray, but not as to that of the others. The public attention was, however, fixed on the red protuberances and the other phenomena of the eclipse, and little notice was evidently taken of the corona.

N. A. Graydon

Hastings, Hawkesbay, New Zealand, September 25

Ophthalmologic Education in the United Kingdom

I did not see your notice of my translation of Fuchs's "Causes and Prevention of Blindness" until to-day. I find two accusations brought against me, which I do not admit to be well founded.

(1) I am accused of "mistranslation" because I have often rendered "Augenheilkunde" by the word "ophthalmology." You state that "the treatment of diseases of the eyes' would be the correct translation. "Ophthalmic medicine," which is my alternative translation, is more correct than the translation you offer; but ophthalmology is quite sufficiently correct, and in many cases is employed by the author indifferently with "Augenheilkunde," to express the same thing. No doubt "ophthalmology," etymologically considered, is a more comprehensive word than "Augenheilkunde" or its English synonym "ophthalmic medicine;" but custom has sanctioned its employment in the limited sense of the latter word in Germany, in France, and in this country. Thus the Professor of Ophthalmic Medicine in Vienna was Professor of Ophthalmology. Fuchs constantly speaks of "ophthalmological clinics," and in many of the medical schools of this country the lecturers on what is in other schools called "ophthalmic surgery," "diseases of the eye," &c., are called lecturers on "ophthalmology" (King's College, Yorkshire College, Liverpool University College, Owens College, Catholic University School of Medicine, Dublin).

(2) I am blamed for not correcting Fuchs when he says, "As a rule no regular lectures on ophthalmology (Augenheilkunde)

are delivered in the medical schools of Great Britain and Ireland." You say: "Systematic lectures are delivered in every medical school in the United Kingdom; and it is difficult to believe that the translator could have been unacquainted with the fact." Now, I do not admit that it is the duty of a mere translator to correct all the errors of the original, and, as a matter of fact, I have, I think, only once put the author right (at p. 109); but I do not admit the author to be wrong in his assertion. Looking through the *Medical Directory* for this year, I find that eleven medical schools make no provision whatever for ophthalmological instruction, and I doubt very much if the "Ophthalmic Demonstrations," "Clinical Lectures on Diseases of the Eye," "Ophthalmic Surgery," &c., advertised at many of the other schools, would properly come under the head of Dr. Fuchs's "regular lectures," or the "systematic lectures" you speak of. As it is upwards of forty years since I was a student at a medical school, I may of course be mistaken respecting the present state of ophthalmologic education in this country; at all events, I had not any knowledge of an opposite state of things which would have enabled me to say that Dr. Fuchs was wrong in saying that "*as a rule* no regular lectures on ophthalmology are delivered" in our medical schools, and the facts I have given above seem to prove that "regular lectures" on ophthalmic medicine are still the exception in the medical schools of the United Kingdom.

R. E. DUDGEON

53, Montagu Square, November 4

[We have referred Dr. Dudgeon's letter to the writer, who replies as follows:—

Dr. Dudgeon's letter will not bear a moment's examination.

In the first place he misstates what he calls the "first accusation." He was not accused of "often" rendering "Augenheilkunde" by "Ophthalmology," but of having done so in one particular place, in which the effect of the mistranslation was to give a certain amount of colour to a statement which, in the original, was wholly untrue.

It is obvious that "Ophthalmology" is neither English, French, nor German. It is common to all three, and the forms of it differ only in termination. "Ophthalmologie" should be rendered by "ophthalmology," and *vice versâ*. Its meaning embraces everything appertaining to the eyes, and its German equivalent is "Augenlehre."

"Augenheilkunde," on the other hand, is a word of limited significance, the meaning of which embraces only the treatment of affections of the eyes. Dr. Dudgeon's suggested rendering, "Ophthalmic Medicine," is so far inadequate that it might not be understood to include surgery, and it could hardly be understood to include the use of optical appliances. "Augenheilkunde" forms part of ophthalmology, an important part indeed, but a part only.

Dr. Fuchs asserted that, "as a rule, no regular lectures on 'Augenheilkunde' were delivered in the medical schools of Great Britain and Ireland." This assertion, very possibly made in honest ignorance, is absolutely the reverse of the truth. Dr. Dudgeon altered it into the statement that "no regular lectures on ophthalmology" were so delivered. This, in a sense, is true; because the lectures, which cover the whole extent of "Augenheilkunde," neither cover, nor attempt to cover, "ophthalmology."

I do not think it is too much to expect that a translator shall correct a misstatement in the original work, especially when that misstatement is one which casts a wholly unmerited stigma upon the institutions of the translator's native country. Instead of correcting it, Dr. Dudgeon casts it into an altered form, in which it may be said to be true literally, although calculated to produce an entirely erroneous impression upon the reader.

Dr. Dudgeon must not go to the extremely condensed statements of the *Medical Directory* for complete accounts of the work done by British Schools of Medicine, but to the prospectuses of the schools themselves. There are thirteen such schools in London, and regular lectures on "Augenheilkunde" are delivered at all of them; at Bartholomew's by Messrs. Power and Vernon; at Guy's by Mr. Higgins and Dr. Brailey; at King's College by Mr. MacHardy; at the London by Mr. Waren Tay; at the Middlesex by Mr Lang; at St. George's by Mr. Brudenell Carter and Mr. Frost; at St. Mary's by Mr. Critchett; at St. Thomas's by Mr. Nettleship; at University College by Mr. Tweedy; at the Westminster by Mr. Cowell; at the West London by Mr. Vernon; at the School of Medicine for Women by Mr. Mackinlay. At Charing Cross the lectures are delivered by arrangement with the staff of the adjacent Westminster Ophthalmic Hospital. It would be tedious to enter into particulars with regard to the provincial, Scotch, and Irish schools, but similar lectures are delivered in all of them.]

The Helm Wind

THE *helm wind* of Cumberland has been the subject of much discussion in England. I wonder how the true explanation has not been found, viz. *that the helm wind is a bora, i.e.* identical in character with the extremely strong dry east and north-east winds blowing on the coasts of Istria and Dalmatia, as well as on the north part of the east coast of the Black Sea, especially at Novorossiisk. At the latter place it blows from the Varada chain, about 2000 feet high, and, as with the helm wind, it is not felt a little distance to the east. I give the translation of a passage on the bora in my book on "The Climates of the World":—

"Seamen call the bora an *air-waterfall*. There is reason to believe that it begins when the stable equilibrium between the air-strata on the mountain and the bay is disturbed, *i.e.* when the latter is more than 10° warmer than the former. The Varada chain falls in a gentle slope eastward towards the broad Adegoa valley, to the north-east of which is the Svinzovy (Lead) chain. In this walled-in valley the temperature is much lower than on the coast, especially in winter and autumn, and when the cold air fills it to overflowing there arises an unstable equilibrium towards the west, and the colder it is on the mountain in comparison to the bay, the stronger is the reaction, *i.e.* the bora."

Here also the bora may arise, not only on account of a strong local cooling of the air in the Adegoa valley, but also accompany general north-east winds to the north of the Caucasian chain. They bring cold air from afar, are sometimes prevented by the Varada chain from sinking to the sea-level, and during this time the equilibrium is disturbed and they appear as bora, even if they blow as gentle farther to the east.

I have no doubt the English helm wind is also due to a disturbed equilibrium. The east is colder than the west, and the contrast is stronger when east winds blow, *i.e.* local radiation makes the east yet colder, and in short a difference of temperature of about 14° is likely to occur between the Cross Fell Range and the Penrith valley. In summer the wind is not felt—the west being then colder than the east; and it is less frequent in winter than in November, March, and April, because the prevailing west winds and the cloudy weather which necessarily accompanies them equalise the temperature.

St. Petersburg, October 19 [31] A. WOEIKOF

The Resting Position of Oysters

THE evidence adduced by Mr. Cunningham to prove that oysters rest on the right or flat valve in their natural state seems conclusive. Remembering, however, that I possessed a young oyster-shell detached from a sandstone rock years ago on the coast of Arran, I turned to it, and was surprised to find that the lower or attached valve was unmistakably the larger, overlapping the other at the hinge and all round. I have another single valve of some foreign species taken from a Haliotis shell, which furnishes similar evidence. Apparently, therefore, in the young or attached state it is the larger or convex valve which is the lower, and probably this is the evidence on which the ordinary statement in conchological books rests. It will be curious if the truth turns out to be that the oyster changes its position when it becomes unattached. Perhaps the remarkable inequalities in the shape of the convex valves may arise from the inequalities in the objects to which they are originally fixed.

W. TURNER

27, Queen's Crescent, Edinburgh

The Australian Lyre Bird

HAVING been stationed at intervals for some years on the mountains of Eastern Manaro, in the southern part of New South Wales, the habitat of the Lyre Bird or Native Pheasant (*Menura superba* or *Paradisea*), I have thought some fuller particulars regarding its habits, than are usually obtainable, might be interesting to your readers.

This range of mountains, the more sheltered sides of which form the home of these interesting birds, attains a height of over 4000 feet above sea level. The sides, sloping towards the coast at a general angle of about 45°, are heavily timbered with eucalypti, wattle, and musk trees, and covered with a dense undergrowth of ferns and creepers, the gullies being filled with tree ferns. Generally speaking there is a noticeable absence of game, but at certain seasons the forest resounds with the varied cries of the male lyre bird. The hen builds her nest at the foot of a trunk of a tree, of twigs and bark, lining it with dried ferns and grass, and leaving an opening in the front of the top. Herein she deposits the *one* egg on which she sits to incubation (for, as an Irish friend said, "she only lays one egg at a time"), leaving the nest daily for food. The country abounds in the hills of ants, from those of the large bull-dog ant, an inch long, to those of a small black variety, and it is upon these insects and their larvæ that the lyre bird chiefly subsists. The bird is of a sooty black colour, with a body somewhat larger than that of a pigeon, but has a tail of graceful form and beautifully marked. Ordinarily, this tail is simply carried behind like a peacock's in repose, but if found upon their "dancing beds" with head erect and tail expanded over the back they are decidedly handsome. These "dancing beds" are patches of comparatively clear ground, from one to two yards in diameter, with the ferns trodden smoothly upon the surface, upon which the birds assemble, and dance and strut to their apparent great delight. The original cry or call of the lyre bird is a very simple one, but his adopted one partakes of that of every sound he hears; for he is a most wonderful mocker, not only of other birds, such as the parrot, cockatoo, yang yang, or magpie, but he will imitate, to the life, the bullock driver with his whip, the step of the teamster's horses, the rasping of the cross-cut saw, and the blows of the axe and tomahawk, and more wonderful still, more than one of these at the same time, so that the solitary explorer is led to believe he has suddenly come upon pioneers of civilisation in the heart of the forest.

The male bird is exceedingly pugnacious, and this fact is made use of by the settlers to his destruction, for his tail is worth $3. By imitating one of his prominent calls, the hunter can lure him within gun-shot, although naturally very shy; he comes to repel a fancied intruder into his domain. His flesh is very dark-coloured and coarse, and only used as food in cases of necessity. Many attempts have been made to rear the birds in captivity, and there is a report that *one* has been successful. With this exception, which I cannot authenticate, I never heard of any result but failure.

The sound of his call so alters in proportion as his tail is in full feather or indifferently ornamented, that hunters can judge from that whether or no any individual bird is worth pursuit.

My apology for asking for so much of your valuable space must be in the fact that until I set myself the task of getting the above information, I could not obtain it from published accounts.

ALFRED MORRIS

Railway Survey Camp, Manaro, New South Wales, September 1

Blackberry Blossoms in November

I HAVE this day seen blackberry blossoms in a hedge on this road, and yet the autumn has been rainy and inclement.

JOSEPH JOHN MURPHY

Osborne Park, Belfast, November 10

EXPLORATIONS IN PAHANG

PAHANG is a small state in the Malay peninsula on the eastern side of the dividing range, with a coast-line on the China Sea. The territory is almost exclusively occupied by Malays, who live on the banks of the rivers; but in the unexplored forests of the interior near the mountains there are a few tribes of wild aboriginal Sakeis. Though Pekan, the capital, is not quite 200 miles from Singapore, it is rarely visited by Europeans. It is situated at the mouth of the river Pahang, and on this stream the bulk of the population is to be found. The Pahang is the main artery of communication with the interior. Its course is inaccurately laid down on the map published by the Straits Government in 1879. Quite recently, however, Mr. W. Cameron, a surveyor, has by his own efforts, unassisted by the Government, mapped the whole course of the stream, and his map, not yet published, is in the hands of the Straits branch of the Royal Asiatic Society. Recently also the river was ascended by Mr. G. Scaife. He went up by the Semanten River and one of its tributaries to the dividing range, and then, accompanied by Malays only, he crossed to Klang, in Selangor, in three days, and so reached the western coast. In May of this year Mr. Swettenham, the Government Resident in Selangor, succeeded in passing the dividing range from Perak by ascending the River Slim. Having descended on the eastern side of the mountains he reached the Lipis River, down which he came on rafts to the Pahang, and so on to Pekan. The whole journey occupied one month.

It may seem strange that a territory so near Singapore should be so little known. The reasons for this are that on the land side its jungles and forests are very inaccessible, and that for six months of the year, when the north-east monsoon is blowing, the rivers and coast-line can scarcely be approached from the sea. Pahang has always had a peculiar interest because of the large and rich gold mines said to exist within its limits. Curious specimens of nuggets are constantly reaching the British settlements from this locality.

In July last I started from Singapore with the intention of seeing some of the gold fields and generally to examine the geology of the river and some of its tributaries. I was accompanied by Mr. H. G. James and Mr. Scaife. A small steam launch had been sent on previously, and we hoped by its means to save time and the inconvenience of depending on native boatmen.

Pekan, the capital, lies about six miles above the mouth of the river. It is a small town of perhaps 1500 inhabitants. It is well laid out in rectangular grassy streets. The sides of these are formed of high bertane fences, within which, buried in tropical foliage, are the detached bungalows of the inhabitants; the houses are built high off the ground with attop roofs. There is one street of wretched Chinese shops called the market. In the midst of this is a somewhat pretentious two-story palace for the Sultan. Close by are many sheds built for games for royal diversion, amid which is a conspicuous inclosure covered in, where for many hours almost daily his Highness plays at top-spinning with his nobility and gentry.

He received us courteously at midnight (a common hour for receptions) and seemed quite pleased to have his country visited by Europeans. He gave us a letter commanding all chiefs (Datus) to give us any help we might require. He does not affect any royal splendour, but is very simple in his habits. He is a liberal-minded man, who might do much but for his indolence.

We started with a party of thirteen in a large river prahm, in case the launch should fail us, which it promptly did. Though only drawing 2 feet 8 inches we lost four days in advancing fifteen miles. At last the shallows stopped us altogether, and we had to take to the prahm. The Pahang drains an immense basin and is fed by innumerable tributaries, so that it is rather disappointing to find that unless in times of flood it is only navigable for the small prahm of the Malay. The largest of these scarcely draws two feet of water.

The channel is from 300 to 600 yards wide, interrupted continually by jungle islands and large sandbanks. On the latter pea-fowl (*Pavo javanicus*) are commonly seen. The banks are lined at intervals with small villages. They may be known at a distance by the clumps of cocoa-nut and betel palm. On our approach we frequently heard the wooden gong or drum echoing with singular clearness through the forest. It reminded one of what Stanley tells us of the River Congo, except that the Pahang natives are very peaceable. The vegetation was of the usual Malay character. The common trees were Ficus, Phyllanthus, Vitex, Castanopsis, Garcinia, Dipterocarpus, Fagræa, Hibiscus, &c., with creepers and vines innumerable, especially Bauhinia, Vitis, Ipomæa, Entada, and Mucuna. I saw very little that was new to me, but there was no time for any search. At forty miles we came to the River Lint, which at one time had a great reputation for its gold mines. Two Europeans have started to prospect the locality. We met with them on our return. They had found traces of very extensive workings in former times, but the whole are quite abandoned. The country around is hilly, and the banks of the river are beautifully picturesque. Scarcely any natives live in the vicinity.

We passed many small tributaries to the right and left, and at ninety-one miles, or eight days, from Pekan passed the Semanten, a large affluent coming from the west. Our course had been west hitherto, but now turned to the north-west. Our progress was but slow. We had hired a second boat, and both had to be urged against a strong current by means of long poles—the usual mode of up-stream progress in the Malaysia. One seldom averages more than a mile an hour in this way.

At about 130 miles we passed the Tomoleng, a large stream to the right. It was up this, I believe, that Baron Maclay passed in 1875. The river to the left is called the Jelis or Jelai. Between the two there is a very small stream which is called the Pahang. In Cameron's map the Jelai is marked as the Pahang, but the natives do not call it so. The Jelis is still a fine river, with fewer sandbanks, and I think a deeper bed. Fifty miles further we reached the Lipis. Where we left the Jelis it was still an important stream at least 200 yards wide. The Lipis is also a good stream, half the width of the former. We only went about ten miles up it, and at that distance or less came to Punjom, a large village, the second in importance to Pekan. We found that the cholera had just visited the place, and carried off half the inhabitants, and we found subsequently that several other villages had been visited, or were actually suffering from this terrible epidemic.

About three miles from Punjom is a celebrated gold mine at a village called Jelai, which has been worked for centuries. The formation is just like what is seen in the auriferous districts of Australia—that is to say, highly inclined slate schists and sandstones with quartz lodes containing the gold. The mines, I am told, have been worked in succession by Siamese, Malays, and Chinese. At present about thirty Chinese are employed, with a few Malays, who wash the sands for gold dust. The locality is very curious, from the evident antiquity of the workings. An enormous quantity of material has been quarried away, and shafts have been sunk in the solid rock. Subsequently the rock has been removed, leaving traces of the shafts on the faces of the quarries. It seems as if the miners had found gold in the alluvium, and then had removed the rock in searching for more. The lodes were scarcely touched, probably being too hard. But just beside the lodes the casing with some pockets of pyrites have been taken out in small quantities and are still worked. Doubtless these ores are rich, but a small quantity of free gold dust is all that these miners get.

The ground for acres around is covered with refuse heaps, and after each rainfall the native women and children may be seen searching for specks of gold in the sand. There is a good deal of iron pyrites in the heaps, and as this gradually decomposes, the gold is liberated in the form of fine dust. The mine is about to be worked by a European company.

I returned from Punjom down the Pahang as far as the Semanten, and ascended that river almost due west for about 50 miles. It then forks into the Karau (W.N.W.) and the Brentong (S.W.). As the latter was a series of rapids we changed our boats for small canoes. The water is very deep in places, but shallow at the rapids, where it falls over barriers of beautiful black marble with white veins, or over slate rocks, highly inclined and much jointed. It took us a whole day to ascend about 15 miles, as there was a fresh in the stream. This made the work of poling up the rapids difficult and exciting. After the first few miles we saw no habitations, but we met small bamboo rafts carrying down ingots of tin from the village of Brentong. The river flows in a channel about 50 yards wide, through a dense forest echoing with the cry of the large black siamang or gibbon monkey (*Hylobates syndactylus ?*). Occasionally we heard the peculiar warning shriek, as I may call it, of the wild aboriginal Sakei.

We left our canoes at the junction of a mountain torrent called the Dua. Here we camped one night, and then crossed to the sources of the stream, passing over several high mountain spurs from the main divide. In the mountains we found a few Malays washing stream tin from a shallow, coarse gravel. This consisted of broken Palæozoic slates and sandstones. We visited two or three mines of this kind in various places in the ranges. Travelling was very difficult, because of the undergrowth amid a fine forest of Dipterocarpus, oak, chestnut figs, Dammar, Fagræa, &c., with much Bertam palm (Huguessonia). Traces of tigers and elephants numerous. Game plentiful. In the river a very large barbel and a smaller one abundant (*Barbus burmanicus* and *Kolus ?*), both tasteless fishes and full of bones. We found also an eel-like voracious fish, which I took to be *Ophiocephalus micropeltes*, excellent eating, but uncommon. I have found the same fishes in all the mountain rivers of the Malay peninsula.

We returned direct to Pekau from the Sungei Dua, having spent about five weeks in the boats. Throughout we found the people affable and courteous, not timid of strangers, though some of them had never previously seen white men. Their only medium of exchange is a tin coinage, shaped for the most part like an old-fashioned square inkstand. They objected to receive the smaller silver coin of the Straits Settlements, but would take an empty bottle or a meat or biscuit tin in exchange for a fowl, and fruit such as bananas, cocoa-nuts, mangostems, and papaws, besides tapioca, maize, and brinjals.

We saw a few slaves, who seemed to be Sakeis or Africans. The whole population of the State can scarcely be 50,000, of which probably not 500 are Chinese.

About half way between the dividing range and the sea there is a belt of detached conical steep mountains 1500 to 2000 feet high. From the specimens of rock abutting on the River Pahang I judge these hills to be volcanic, and to consist of trachytic and felspathic rocks. I also found in the bed of the stream isolated patches of andesite, felsite, molaphyre, and limestone. In respect to the volcanic rocks the eastern side of the Malay peninsula differs much from the western. J. E. TENISON-WOOD

Singapore, August 28

P.S.—I have just seen in a number of NATURE, published in the early part of this year, a letter from Mr. L. Wray, jun., correcting what he considers certain mistakes of mine. It is due to your readers to state that I do not accept any of these corrections. During the long period that I have spent in exploring in these regions, Mr. Wray travelled with me for about a fortnight. I should like to repeat that I have never seen on the Malay peninsula any sign of upheaval or subsidence. The instance Mr. Wray refers to at Matang obviously admits of a very different interpretation.

THE CRETACEOUS FLORAS OF CANADA[1]

Geological Relations of the Floras

IN a memoir published in the first volume of the *Transactions* of this Society I have given a table of the Cretaceous formations of the western North-

[1] By Sir William Dawson, F.R.S., &c. From advance sheets of a memoir to appear in the *Transactions* of the Royal Society of Canada.

West Territories of Canada, prepared by Dr. G. M. Dawson, and have fully stated the geological position of the plants at that time described. The new facts detailed now require us to intercalate in our table three distinct plant-horizons not previously recognised in the western territories of Canada. One of these, the Kootanie series, should probably be placed at the base of the table as a representative of the Urgonian or Neocomian, or, at the very least, should be held as not newer than the Shasta group of the United States Geologists, and the Lower Sandstones and Shales of the Queen Charlotte Islands. It would seem to correspond in the character of its fossil plants with the oldest Cretaceous floras recognised in Europe and Asia, and with that of the Komé formation in Greenland, as described by Heer. No similar flora seems yet to have been distinctly recognised in the United States, except, perhaps, that of the beds in Maryland, holding cycads, and which were referred many years ago by Tyson to the Wealden.

The second of these plant-horizons separated, according to Dr. G. M. Dawson, by a considerable thickness of strata, is that which he has called the Mill Creek series, and which corresponds very closely with that of the Dakota group, as described by Lesquereux, and that of the Atané and Patoot formations in Greenland, as described by Heer. This fills a gap, indicated only conjecturally in the table of 1883. Along with the plants from the Dunvegan group of Peace River, described in 1883, it would seem to represent the flora of the Cenomanian and Turonian divisions of the Cretaceous in Europe.

Above this we have also to intercalate a third sub-flora, that of the Belly River series at the base of the Fort Pierre group. This, though separated from the Laramie proper by the marine beds of the Pierre and Fox Hill groups, more than 1700 feet in thickness, introduces the Laramie or Danian flora, which continues to the top of the Cretaceous, and probably into the Eocene, and includes several species still surviving on the American continent, or represented by forms so close that they may be varietal merely.

Lastly, the subdivision of the Laramie group, in the last Report of Dr. G. M. Dawson, into the three members known respectively as the Lower or St. Mary River series, the Middle or Willow Creek series, and the Upper or Porcupine Hill series, in connection with the fact that the fossil plants occur chiefly in the lower and upper members, enables us now to divide the Laramie flora proper into two sub-floras—an older, closely allied to that of the Belly River series below; and a newer, identical with that of Souris River, described as Laramie in Dr. G. M. Dawson's Report on the 49th Parallel, 1876, and in the Report of the Geological Survey of Canada for 1879, and which appears to agree with that known in the United States as the Fort Union group, and in part at least with the so-called Miocene of Heer from Greenland.

From the animal fossils and the character of the flora it would seem probable that the rich flora of the Cretaceous coal-fields of Vancouver Island is nearly synchronous with that of the coal-bearing Belly River series of the western plains.

It will thus be seen that the explorations already made in Canadian territory have revealed a very complete series of Cretaceous plants, admitting, no doubt, of large additions to the number of species by future discoveries, and also of the establishment of connecting links between the different members, but giving a satisfactory basis for the knowledge of the succession of plants and for the determination of the ages of formations by their vegetable fossils.

The successive series may be tabulated as follows, with references for details to the fuller table in my memoir of 1883:—

Successive Floras and Sub-Floras of the Cretaceous in Canada (in Descending Order)

Periods	Floras and Sub-Floras	References
Transition Eocene to Cretaceous	Upper Laramie or Porcupine Hill Series ...	Platanus beds of Souris River and Calgary. Report Geol. Survey of Canada for 1879, and memoir of 1885.
Upper Cretaceous (Danian and Senonian)	Middle Laramie or Willow Creek Series.	
	Lower Laramie or St. Mary River Series ...	Lemna and Pistia beds of bad lands of 49th Parallel, Red Deer River, &c., with Lignites. Report 49th Parallel and memoir of 1885.
	Fox Hill Series	Marine.
	Fort Pierre Series	Marine.
	Belly River Series. (See note.)	Sequoia and Brasenia beds of S. Saskatchewan, Belly River, &c., with Lignites. Memoir of 1885.
	Coal Measures of Nanaimo, B.C., probably here ...	Memoir of 1883. Many Dicotyledons, Palms, &c.
Middle Cretaceous (Turonian and Cenomanian)	Dunvegan Series of Peace River. (See note.) ...	Memoir of 1883. Many Dicotyledons, Cycads, &c.
	Mill Creek Series of Rocky Mountains	Dicotyledonous leaves, similar to Dakota Group of the U.S. Memoir of 1885.
Lower Cretaceous (Neocomian, &c.)	Suskwa River and Queen Charlotte Island Series. Intermediate Series of Rocky Mountains ...	Cycads, Pines, a few Dicotyledons. Report Geol. Survey. Memoir of 1885.
	Kootanie Series of Rocky Mountains	Cycads, Pines, and Ferns. Memoir of 1885.

NOTE.—Though the flora of the Belly River Series very closely resembles that of the Lower Laramie, showing tha similar plants existed throughout the Senonian and Danian periods in North America, yet it is to be anticipated that specific differences will develop themselves in the progress of discovery. In the meantime it scarcely seems possible to distinguish by fossil plants alone the Lower Laramie beds from those of Belly River, and if these are really separated by 1700 feet of marine strata, as is now believed on stratigraphical grounds, the flora must have been remarkably persistent. The Dunvegan series of Peace River probably corresponds in time with the marine Niobrara and Benton groups farther south, and the Mill Creek with the Dakota group

Physical Conditions and Climate indicated by the Cretaceous Floras.—In the Jurassic and earliest Cretaceous periods the prevalence, over the whole of the Northern Hemisphere, and for a long time, of a monotonous assemblage of Gymnospermous and Acrogenous plants, implies an uniform and mild climate and facility for intercommunication in the north. Towards the end of the Jurassic and beginning of the Cretaceous, the land of the Northern Hemisphere was assuming greater dimensions, and the climate probably becoming a little less uniform. Before the close of the Lower Cretaceous period, the dicotyledonous flora seems to have been introduced, under geographical conditions which permitted a warm-temperate climate to extend as far north as Greenland.

In the Cenomanian we find the Northern Hemisphere tenanted with dicotyledonous trees closely allied to those of modern times, though still indicating a climate much warmer than that which at present prevails. In this age extensive but gradual submergence of land is indicated by the prevalence of chalk and marine limestones over the surface of both continents; but a circumpolar belt of land seems to have been maintained, protecting the Atlantic and Pacific basins from floating ice, and permitting a temperate flora of great richness to prevail far to the north, and especially along the southern margins and extensions of the circumpolar land. These seem to have been the physical conditions which terminated the existence of the old Mesozoic flora and introduced that of the Middle Cretaceous.

As time advanced, the quantity of land gradually increased, and the extension of new plains along the older ridges of land was coincident with the deposition of the great Laramie series and with the origination of its peculiar flora, which indicates a mild climate and considerable variety of station in mountain, plain, and swamp, as well as in great sheets of shallow and weedy fresh water.

In the Eocene and Miocene periods the continent gradually assumed its present form, and the vegetation became still more modern in aspect. In that period of the Eocene, however, in which the great nummulitic limestones were deposited, a submergence of land occurred on the eastern continent which must have assimilated its physical conditions to those of the Middle Cretaceous. This great change, affecting materially the flora of Europe, was not equally great in America, which also by the north and south extension of its mountain chains permitted movements of migration not possible in the Old World. From the Eocene downwards, the remains of land animals and plants are found only in lake basins occupying the existing depressions of the land, though more extensive than those now remaining. It must also be borne in mind that the great foldings and fractures of the crust of the earth which occurred at the close of the Eocene, and to which the final elevation of such ranges as the Alps and the Rocky Mountains belongs, permanently modified and moulded the forms of the continents.

These statements raise, however, questions as to the precise equivalence in time of similar floras found in different latitudes. However equable the climate, there must have been some appreciable difference in proceeding from north to south. If, therefore, as seems in every way probable, the new species of plants originated on the Arctic land and spread themselves southward, this latter process would occur most naturally in times of gradual refrigeration or of the access of a more extreme climate, that is, in times of the elevation of land in the temperate latitudes, or conversely, of local depression of land in the Arctic, leading to invasions of northern ice. Hence the times of the prevalence of particular types of plants in the far north would precede those of their extension to the south, and a flora found fossil in Greenland might be supposed to be somewhat older than a similar flora when found farther south. It would seem, however, that the time required for the extension of a new flora to its extreme geographical limit, is so small in comparison with the duration of an entire geological period, that practically, this difference is of little moment, or at least does not amount to antedating the Arctic flora of a particular type by a whole period, but only by a fraction of such period.

It does not appear that during the whole of the Cretaceous and Eocene periods there is any evidence of such refrigeration as seriously to interfere with the flora, but perhaps the times of most considerable warmth are those of the Dunvegan group in the Middle Cretaceous and those of the later Laramie and oldest Eocene.

It would appear that no cause for the mild temperature of the Cretaceous needs to be invoked other than those mutations of land and water which the geological deposits themselves indicate. A condition, for example, of the Atlantic basin in which the high land of Greenland should be reduced in elevation and at the same time the northern inlets of the Atlantic closed against the invasion of Arctic ice, would at once restore climatic conditions allowing of the growth of a temperate flora in Greenland. As Dr. Brown has shown ("Florula Discoana"), and as I have elsewhere argued, the absence of light in the Arctic winter is no disadvantage, since, during the winter, the growth of deciduous trees is in any case suspended, while the constant continuance of light in the summer is, on the contrary, a very great stimulus and advantage.

It is a remarkable phenomenon in the history of genera of plants in the later Mesozoic and Tertiary, that the older genera appear at once in a great number of specific types, which become reduced as well as limited in range down to the modern. This is no doubt connected with the greater differentiation of local conditions in the modern; but it indicates also a law of rapid multiplication of species in the early life of genera. The distribution of the species of *Salisburia*, *Sequoia*, *Platanus*, *Sassafras*, *Liriodendron*, *Magnolia*, and many other genera, affords remarkable proofs of this.

Gray, Saporta, Heer, Newberry, Lesquereux, and Starkie Gardner, have all ably discussed these points; but the continual increase of our knowledge of the several floras, and the removal of error as to the dates of their appearance must greatly conduce to clearer and more definite ideas. In particular, the prevailing opinion that the Miocene was a period of the greatest extension of warmth and of a temperate flora into the Arctic, must be abandoned in favour of the later Cretaceous and Eocene; and if I mistake not, this will be found to accord better with the evidence of general geology and of animal fossils.

NOTE.—While this memoir was passing through the press, the Report of Mr. Whiteaves, F.G.S., Palæontologist to the Canadian Survey, on the invertebrate fossils of the Laramie and Cretaceous of the Bow and Belly River districts appeared ("Contributions to Canadian Palæontology," vol. i. part 1, 89 pp. and 11 plates). This valuable Report constitutes an independent testimony, based on animal fossils, to the age of the beds in question, and accords in the main very closely with the conclusions above derived from fossil plants. Unfortunately, however, no animal remains have yet been found in the Kootanie series, and the only fossil recorded from the Mill Creek beds is a species of *Inoceramus* characteristic in the United States of the Niobrara and Benton groups, a position a little higher than that deduced from the plants.

RADIANT LIGHT AND HEAT[1]

IV.

Radiation and Absorption—Celestial Applications.

THE continuous emission of light and heat from the sun and stars through long periods, consisting of millions of years, cannot fail to strike us with amazement, more especially if we regard the great intensity of this radiation. It has been conjectured that the amount of solar heat received by the earth in one year would liquefy a layer of ice 100 feet thick, covering the whole surface of the earth. Now if we bear in mind that the solar heat reaching the earth at any time is only $\frac{1}{2300000000}$ of that which leaves the sun, we may obtain some conception of the enormous radiation from our luminary. It has been calculated by Sir William Thomson that if the sun were a hot solid body, such as carbon, its surface would cool in a few minutes of time. It therefore becomes an object of great scientific interest and importance to discover what is the nature of the peculiar machinery which enables the sun to continue, without interruption, discharging, as it does, into space such enormous quantities of radiant energy. The reply to this question can best be given by a detailed study of the surface of the sun. Whether viewed telescopically or spectroscopically, this

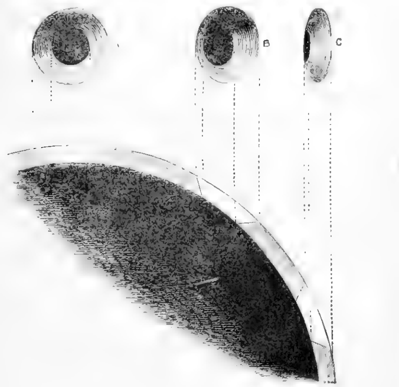

FIG. 11.

surface is by no means that of a globe of uniformly luminous heated matter. Let us begin by examining this surface telescopically.

Shortly after the invention of the telescope Galileo and Scheiner showed that the disc of the sun is far from being uniformly luminous, since it frequently presents the appearance of having large *spots* on its surface. This is a fact which had been previously known to the Chinese. Further research showed that these black spots exhibit at least two degrees of darkness, consisting of a central intensely dark *umbra*, surrounded by a *penumbra*, or semi-dark border. We know now that even the umbra is not absolutely black, but consists of matter at a temperature comparatively low as regards the sun, but comparatively high as regards the earth. It was likewise found in the course of telescopic research that there are patches which are brighter, not darker than the average solar surface or *photosphere*, and these bright patches have been termed *faculæ*.

Thus we have on the solar surface things with three degrees of brightness, consisting of the normal solar surface or photosphere, of the spots which are darker than it, and of the faculæ, which are the brightest of all. The faculæ are more especially to be found in the neighbourhood of spots.

These are the phenomena which may generally be viewed on the sun's surface on any occasion by means of an ordinary telescope. Nevertheless, there are occasions on which we shall find no spots. Schwabe, a German observer, after forty years' patient study of the sun's surface, was successful in detecting a periodicity of these phenomena. There are certain years of maximum and other years of minimum sun-spot frequency, and the average distance from one maximum to the next, or from one minimum to the next, is about eleven years.

FIG. 12.

I have said nothing hitherto about the rotation of the sun, which was discovered by means of the apparent motion of the sun spots over the solar disc. This rotation takes place in about twenty-six days, and its plane is not far removed from the ecliptic, or that in which the earth moves around the sun, the two motions being likewise in the same direction. It has been discovered by Carrington that, as a rule, spots are confined to the regions around the solar equator, never by any chance appearing at the poles.

The nature of these spots has been a subject of much

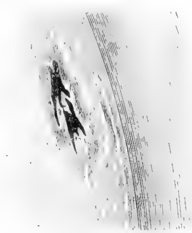

FIG. 13.

discussion. Professor Wilson, of Glasgow, was the first to bring forward evidence indicating that they are below the general level of the solar surface—pits, in fact, the bottoms of which are intensely black, while the sloping sides are less so. This evidence consisted in the fact that when near the sun's border that portion of the penumbra of a spot which is next the visual centre is hidden from our view, a behaviour which is illustrated in Fig. 11. Again, it has been pointed out by the Kew observers that the bottom of a spot is blacker because it is colder than the general surface, and they have likewise brought forward evidence to show that this diminution of temperature has

[1] Continued from vol. xxxii. p. 551.

probably been produced by the downrush of comparatively cold matter from above, a conclusion which has since been abundantly verified by spectroscopic observations.

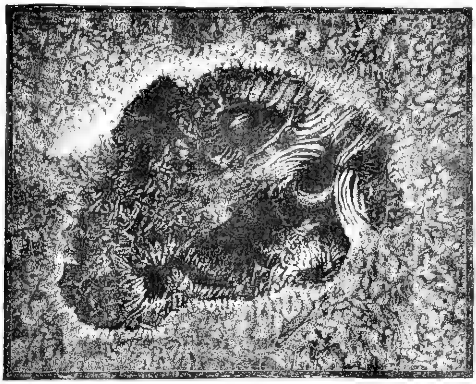

Fig. 11.

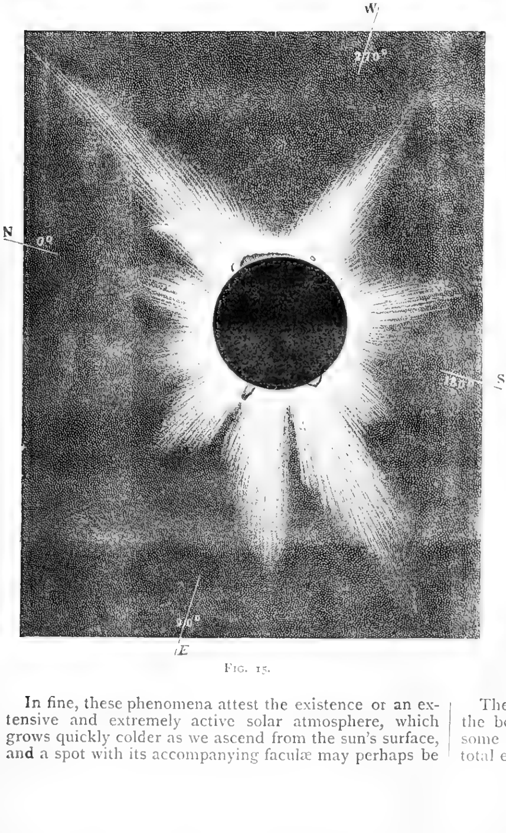

Fig. 15.

In fine, these phenomena attest the existence of an extensive and extremely active solar atmosphere, which grows quickly colder as we ascend from the sun's surface, and a spot with its accompanying faculæ may perhaps be looked upon in the light of a celestial hurricane or hail-storm.

We have in the spot the downrush of a vast quantity of comparatively cold matter from above, and in the faculæ the necessary re-action of this, or the uprush of comparatively hot matter from below, the scale of the operation being occasionally of such a vast magnitude that thirty or forty of our earths might be buried in the pit which represents a spot.

What we have on a large scale in spots and faculæ we have on a small scale all over the sun's disc. When viewed with a powerful telescope the brightness of his disc is found to be far from uniform, the whole surface being made up of bright and dark patches existing side by side. This mottled appearance was first noticed by the elder Herschel, who considered the pores, as he termed them, to be small spots—a conclusion which has since been abundantly verified by the spectroscope. Quite recently M. Janssen, the well-known French observer, has obtained admirable photographs of the sun, exhibiting this mottled appearance on a very large scale. In Fig. 12 we have a picture of a cyclonic sun spot, while in Fig. 13 we have one of faculæ surrounding a spot seen near the sun's edge. Fig. 14 again is a picture by Secchi exhibiting the general mottled appearance round a spot, and the lengthening out of the irregular masses into "straws" in the penumbra.

The phenomena which I have just described are those which are seen projected upon the solar disc. I now go on to describe those which take place near his border. On the occasion of total solar eclipses *red flames*, or *prominences*, are seen to surround the darkened disc of our luminary. At first it was not known whether these belonged to the sun or not, but we are now quite certain that they are true solar appendages. On the same occasions we have, in addition to the red flames, a solar *corona*, or glory, extending sometimes to a very great distance around the solar disc, perhaps even a million of miles or more. Recent observation has proved that this corona is likewise, in part, at least, an undoubted solar appendage.

Having now described the results given us by telescopic observation, let me proceed to those which the spectroscope reveals. Allusion has already been made to the dark lines which occur in the solar spectrum, and which form the characteristic difference betwixt his spectrum and that of the electric light. We have also mentioned the fact that the double solar line D corresponds quite exactly in spectral position with the bright lines given out by incandescent sodium, and that Prof. Stokes conjectured from this coincidence that sodium must exist in the solar atmosphere at a comparatively low temperature.

Professors Bunsen and Kirchhoff in their spectroscopic researches greatly extended this branch of inquiry, showing that many of the dark lines of the solar spectrum are coincident in spectral position with bright lines seen in terrestrial spectra, and concluding that the gaseous substances which afford these spectra must occur in a comparatively cold state in the atmosphere of the sun. The following substances have thus been found to occur in the atmosphere of our luminary—hydrogen, magnesium, calcium, sodium, iron, nickel, manganese, chromium, cobalt, barium, copper, zinc, titanium, aluminium.

The spectroscope has been applied with equal success to the border or limb of our luminary. It was a subject of some surprise that the red flames seen at the time of a total eclipse should be invisible on other occasions; and this perhaps induced observers to imagine that they were not true solar appendages. Independently and nearly simultaneously Janssen and Lockyer showed that these red flames may be rendered visible on ordinary occasions by means of the spectroscope, and they are now the daily study of solar observers. It has been shown that they consist chiefly of incandescent hydrogen, and the reason is very obvious why we cannot see them without the spectroscope. The glare of light around the sun's disc

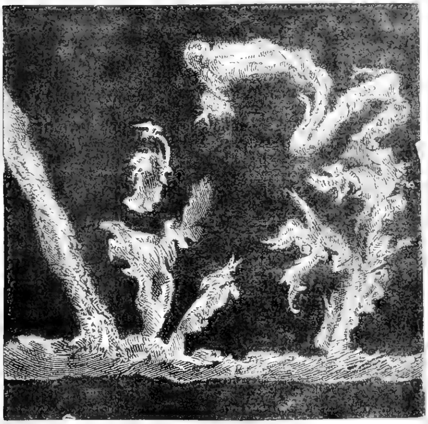

Fig. 16.

(a strictly terrestrial phenomenon due to reflexion) is in general so strong compared to the light from the red flames, that it is impossible for the eye to distinguish the latter. Now during a total eclipse this glare is removed, and hence the eye can see the red flames. But in the spectroscope we have a means not so much of removing as of diluting the glare, while at the same time the light from the red flames is not diluted. This arises from the fact that the glare is ordinary sun-light, consisting of rays of a great many refrangibilities which are spread out into a long ribbon by the spectroscope, and consequently diluted. On the other hand, that from the red flames consists only of one or two widely-separated

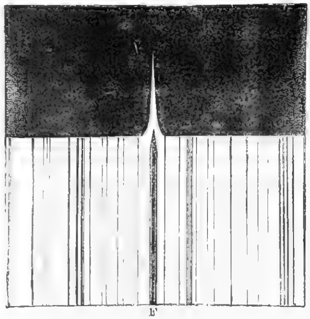

Fig. 17

refrangibilities which are not spread out, and therefore not diluted. The consequence is that the red flames give us a few bright spectral lines standing out in a solar

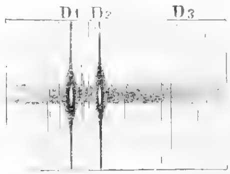

Fig. 18.

spectrum so diluted as to be almost invisible. In Fig. 15 we have a representation of the eclipsed sun showing the red flames near the sun, and the corona extending to a great distance around his disc; while in Fig. 16 we have

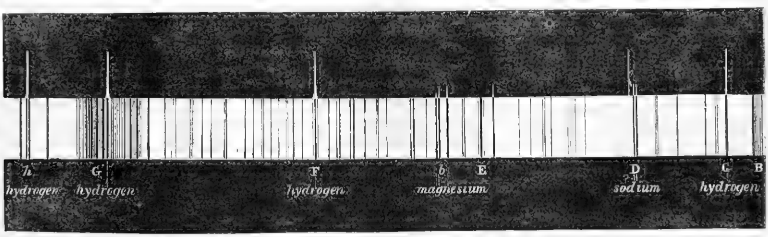

Fig. 19.—Exhibiting the spectrum of the chromosphere above and that of the photosphere below.

an enlarged view of one of the red flames, showing the curious shapes which these phenomena frequently assume.

The application of the spectroscope by Lockyer and others to selected portions of the solar disc and its surroundings has been most fruitful in its consequences.

One of the first results obtained by Lockyer was the arrow-shaped appearance of the bright line F of the sun's atmosphere, when the slit of the spectroscope is made to form a continuation outwards of the solar radius; that is to say, is perpendicular to the rim of the sun.

This is shown in Fig. 17, and the explanation is very simple. It will be remembered that the line F of hydrogen is one which is very susceptible to an increase of pressure. It is therefore much wider at the bottom of the solar atmosphere than at the top, thus presenting the appearance seen in the figure. When the same observer applied the spectroscope to a sun-spot there was found to be a thickening of various absorption lines in the region of the spot, thus indicating an increase of pressure, and proving that a spot is a phenomenon that occurs below the general surface of the photosphere. In Fig. 18 we have the spectrum of a sun-spot as given by Young, exhibiting this thickening in the double line D, a line which, like F, is eminently susceptible to variations of pressure.

It is, however, erroneous to suppose that the solar atmosphere consists entirely of the red prominences already mentioned. These denote merely (as their name indeed implies) the most violently agitated portions of an atmosphere surrounding the whole sun. Lockyer has named this atmosphere the *chromosphere*, and it extends to an average height of about 4000 miles above the surface of the sun. In Fig. 19 we have a picture of the spectrum of the sun's photosphere below and of the chromosphere above.

One prominent constituent of the chromosphere is hydrogen, but we have here a very strange circumstance. Besides certain well-known hydrogen lines, we have in the chromosphere spectrum an orange-yellow line near D, which we cannot identify with the spectrum of any terrestrial substance. It is probably due to some unknown gaseous body which is mixed up with the hydrogen in the atmosphere of our luminary. Again, in the solar corona, we have a green line which we likewise cannot identify; but our opportunities of examining this region are so few and so transient that any conclusion we may come to with respect to its lines must be regarded as provisional.

BALFOUR STEWART

(*To be continued.*)

BULLETIN OF THE UNITED STATES FISH COMMISSION FOR 1884[1]

TO those who are not already familiar with this publication, it is necessary to explain that the bulletin is a journal whose successive numbers appear at short but irregular intervals, each number containing a small collection of brief articles, notes, and reports, on subjects connected with the work of the Commission. At the end of each year the numbers that have been issued during its course are collected into a single volume and republished.

Some of the notes and articles in the volume for 1884 have but a very remote connection with fish or fisheries, broad as is the interpretation given to those terms by the American Commission. In most cases it may be conceded that the information given has some relation to the supply of human food derived from aquatic organisms, or at any rate some bearing on aquatic life. But it is difficult to see the connection between a report on the sanitary condition of the inhabitants of Old Providence Island and the subject of aquiculture. The Report referred to contains many interesting facts concerning the fecundity, education, and diseases of the people mentioned; it would form a valuable contribution to a medical journal, but the fact that its author was surgeon on board the *Albatross* when he acquired the knowledge of his subject is scarcely sufficient to prevent surprise at the appearance of a sanitary report in the Fish Commission Bulletin.

A considerable proportion of the volume is occupied with reprints and translations from journals and publications of other countries, and nearly all of these are interesting and useful. By the republication of these foreign papers the Bulletin becomes a guide to the knowledge of what is being done in aquicultural enterprise in all parts of the world. Among the reprints are several from British journals—for example, the articles which appeared last year in NATURE on the capture of fish larvæ by Utricularia, and an article on the sea-serpent by Richard A. Proctor, which is taken from the *Newcastle Weekly Chronicle*.

Dr. P. Brecchi's Report on the condition of oyster-culture in France in 1881, originally published in the *Journal Officiel*, is given in full; and there are also several other useful articles on the subject of oyster-culture. Mr. John A. Ryder contributes a description with illustrations of a new sand-diaphragm to be used in the cultivation of oysters in marine ponds, and a report on the condition of the oyster fishery at St. Jerome Creek. Lieutenant Francis Winslow reports on some experiments made in 1883 on the rearing of oyster larvæ. The experiments were not completely successful, and the problem of establishing a working system of oyster-culture on the east coast of America still affords scope for the energies of the Fish Commission.

Several articles and reports contain data from which may be ascertained the extent and success of the efforts which are being made to acclimatise various species of fish in waters far distant from their native homes. The introduction of American fish into French streams has been in many cases successfully accomplished by the Société Nationale d'Acclimatisation. Details of the experiments are given in an article compiled from the monthly bulletin of the Society. Pisciculture and the acclimatisation of new species in Germany is treated in several articles by Max. von dem Borne, who is the founder and owner of a large piscicultural establishment at Berneuchen. The bare record of the successful transmission of whitefish eggs to Nelson, New Zealand, and of American black bass to the river Nene in England, is contained in letters which are reprinted.

Reference to any particular article or subject in the volume, in spite of its extremely heterogeneous character, has been made perfectly easy by the number and completeness of the indexes with which it is provided. In the table of contents the names of all the contributors are given in alphabetical order. A topical synopsis follows, in which the various subjects treated in the articles and notes are given under five headings. Finally, at the end of the book, is an accurate and complete general index.

The *Proceedings* of the United States National Museum is published on the same plan as the *Bulletin* of the U.S. Fish Commission. In the "advertisement" to the volume before us (vol. vii. 1884, Washington, 1885) we are told that the series was commenced in 1878 to provide a means for the prompt publication of descriptions of the new and interesting material which was being sent to the Museum by the activity of the collectors employed in its interest. The articles are published in signatures, one of which is issued whenever printed material to the extent of sixteen pages has accumulated. The produce of each year is issued as an annual volume. The articles consist of papers by members of the scientific corps of the Museum, of papers by others founded on the collections in the Museum, and of interesting extracts from the correspondence of the Smithsonian Institution. The more extensive and complete publications of the Museum are issued in the series of *Bulletins*. Both series are published at the expense of the Interior Department, under the direction of the Smithsonian Institution, and with the supervision of Mr. Spencer F. Baird, director of the National Museum. The present volume, containing a large proportion of articles on fishes, has been edited by Dr. Tarleton H. Bean, curator of the Department of Fishes.

A considerable number of new species of fish are described in this volume. Dr. Bean describes a new species of Coregonus from Alaska, two new species obtained by the Fish Commission, and two from Jamaica. Mr. David Jordan contributes notes on a collection of fishes from Pensacola, Florida, with two new species, one of Exocœtus; and nine other short papers on collections of fishes from Mexico, Florida, and the Mississippi. The same naturalist, in collaboration with Ch. H. Gilbert, gives four, with Seth E. Meek two, and with Joseph Swain six, notes on fishes. The volume contains several additions to the natural history of the Commander Islands in the Behring Sea. One of these is a refutation, by Leonhard Stejneger,

[1] *Proc.* of the U.S. National Museum, vol. vii. 1884. (Washington, 1885.)

of the story reported by Nordenskiöld, that a sea-cow (*Rhytina gigas*) had been seen alive in 1854. There are two plates: one of the Saccopharyngoid *Ophiognathus ampullaceus*, the other of some new shells from Alaska. The index is as complete as usual in American books of this class.

NOTES

THE following is a list of the names which the President and Council of the Royal Society will recommend to the Society at their forthcoming Anniversary Meeting on the 30th inst. for election into the Council for the ensuing year:—President, Prof. George Gabriel Stokes, M.A., D.C.L., LL.D. Treasurer, John Evans, D.C.L., LL.D. Secretaries: Prof. Michael Foster, M.A., M.D., The Lord Rayleigh, D.C.L. Foreign Secretary, Prof. Alexander William Williamson, LL.D. Other Members of the Council: Prof. Robert B. Clifton, M.A., Prof. James Dewar, M.A., Prof. William Henry Flower, LL.D., Archibald Geikie, LL.D., Sir Joseph D. Hooker, K.C.S.I., Prof. Thomas Henry Huxley, LL.D., Admiral Sir A. Cooper Key, G.C.B., J. Norman Lockyer, F.R.A.S., Prof. Henry N. Moseley, M.A., F.L.S., Prof. Bartholomew Price, M.A., Prof. Pritchard, F.R.A.S., William James Russell, Ph.D., Prof. J. S. Burdon Sanderson, LL.D., Prof. Arthur Schuster, Ph.D., Lieut.-Gen. R. Strachey, R.E., C.S.I., General James Thomas Walker, C.B.

WE greatly regret to announce the death, on Tuesday, of Dr. W. B. Carpenter, at the age of seventy-three years. His death, it would seem, was the result of an accident a few hours before. The funeral will take place to-morrow (Friday) at Highgate Cemetery. We hope next week to refer at length to the scientific work of Dr. Carpenter.

A VERY remarkable article appears in the *Nation* of October 29, on "The Private Endowment of Research," remarkable as appearing in a paper like the *Nation*, published in a "practical" country like America. "Society," the *Nation* says, "may not be prepared to interfere with the breeding of great men, but when they have once been sporadically produced there is no reason why it should not concern itself with their careful preservation. In a state of nature there is a sure process for securing the supremacy of the most perfect individuals of a race, but the qualities which make the human being great are not always qualities which fit him for taking part in the vulgar struggle for existence. . . . Huxley has well said that any country would find it greatly to its profit to spend a hundred thousand dollars in first finding a Faraday, and then putting him in a position in which he could do the greatest possible amount of work." To expose a man of genius, according to the *Nation*, "to the same harsh treatment which is good for the hod-carrier and the bricklayer, is to indulge in a reckless waste of the means of a country's greatness. But instead of the rarely-gifted being treated more favourably by the present highly scientific generation, they actually receive less consideration than they have done in many past ages of the world. . . .The waste of water-power at Niagara (the article concludes) is as nothing compared with the waste of brain-power which results from compelling a man of exceptional qualifications to earn his own living. The owner of a great estate admits that the important charities of his town have a well-founded claim upon his purse; it would not require a very great change of heart for him to feel a vivid sense of shame if a few scholars are not carrying on their researches at his expense."

THE following papers (among others) will be read at the Society of Arts during the present Session:—Apparatus for the Automatic Extinction of Fires, by Prof. Silvanus P. Thompson; The Load Line of Ships, by Prof. Francis Elgar, F.R.S.E.; Technical Art Teaching, by F. Edward Hulme, F.L.S.; The Treatment of Sewage, by Dr. C. Meymott Tidy; Calculating Machines, by C. V. Boys; The History and Manufacture of Playing Cards, by George Clulow; Domestic Electric Lighting, by W. H. Preece, F.R.S.; The Scientific Development of the Coal Tar Industry, by Prof. R. Meldola, F.C.S. The First Course of Cantor Lectures will be on "The Microscope," by John Mayall, Jun., on November 23, 30, December 7, 14, 21; the Second Course will be on "Friction," by Prof. H. S. Hele Shaw, on January 18, 25, February 1, 8; the Third Course will be on "Science Teaching," by Prof. F. Guthrie, F.R.S., on February 15, 22, March 1; the Fourth Course will be on "Petroleum and its Products," by Boverton Redwood, F.C.S., on March 8, 15, 22, 29; the Fifth Course will be on "The Arts of Tapestry-Making and Embroidery," by Alan S. Cole, on April 5, 12, 19; and the Sixth and concluding Course will be on "Animal Mechanics," by B. W. Richardson, M.D., F.R.S., on May 3, 10, 17, 24, 31. The two Juvenile Lectures on "Waves" will be given by Prof. Silvanus P. Thompson on Wednesday evenings, December 30, 1885, and January 6, 1886, for which special tickets will be issued.

Science contains accounts by Profs. Mendenhall and Paul of the attempts made to obtain records of earth tremors from the explosion at Flood Rock at the entrance to New York harbour. Arrangements to secure observations were made by the Geological Survey, together with representatives from the Naval Observatory and Signal Service. The apparatus used by the Naval Observatory party was that usual in mercury observations, and three seismoscopes, one chronograph, and a number of chronometers. Unfortunately the firing of the mine was delayed for fourteen minutes, and this prevented good observations being taken at many places. The reports so far received indicate that out of seventeen stations (three occupied by geological survey parties and fourteen co-operating with them) five watched till the disturbance came, and got more or less satisfactory observations. At one of these the rock was directly in sight, and the others were so near that the observers felt sure that it had not escaped them. Four observed and timed some slight disturbances between 11h. 3m. and 11h. 7m., and, attributing them to the explosion, ceased watching for more, and either missed it entirely or were taken by surprise; two heard nothing at all up to about 11h. 10m., and so ceased observing and missed it, and six were yet to be heard from. It will thus be perceived that the results with regard to earth-tremors, which there was every reason to expect from this colossal explosion, have been greatly diminished by the long delay in firing the mine.

PART II. of the Report of the Trinity House Committee on the recent experiments with electricity, gas, and oil as lighthouse illuminants at South Foreland, which is now issued, contains some interesting details in connection with the trials. The first portion is devoted to illustrations of the arrangements made at the South Foreland for exhibiting, observing, and measuring the lights. The second section consists of the report of Prof. W. Grylls Adams, F.R.S., of King's College, London, on the electric light apparatus employed in the production of the light shown from A tower. Following upon Prof. Adams's report is a detailed description by Baron A. de Méritens of the magneto-electric machines supplied by him for the experiments. This communication shows the principles of construction of the machines and the mechanical disposition of the magnets. Section IV. is a detailed record of the photometric observations made by Mr. Harold Dixon, of Balliol College, Oxford, and referred to by him in his report in Part I. The record consists principally of tables showing the work done on each night. Following this are some remarks upon the pentane standard devised by Mr. Vernon Harcourt, and adopted as the basis of measurement throughout the trials. Some interesting experiments to ascertain the effect of different atmospheric pressures upon this flame are described, in connection with which Mr. Harcourt and Mr. Dixon went to the summit of Ben Nevis. They found that the variation in the burning of the pentane flame due to variation in atmospheric pressure was less than had been anticipated, and that consequently no correction for such variation was necessary for the photometric results obtained at the South Foreland. Sections V., VI., and VII. deal with a very important question. A tabular statement is given illustrating the range of temperature within the gas and oil lanterns during the working of the higher power of these illuminants. In the gas lantern three of the four lens panels used to illustrate a fixed light have been seriously damaged, as shown by copies of photographs published. The lowest panel has not suffered. In the oil and electric lanterns the lenses are uninjured. The inference is that the damage has been caused by the direct or indirect action of heat. Section VIII. consists merely of a reproduction of a table from Mr. Thomas Stevenson's work on lighthouse construction and illumination in reference to the penetrating power of lights in relation to the increase of their intensity. Section IX. gives the result of observations made to ascertain the suitability of the respective illuminants for the exhibition of coloured sectors of light. The question of duration of flashes is dealt with in Section X. Under the heading "Divergence of Beam" Section XI. deals further with this question of the size of the beam. Section XII. consists of reports of experiments with sky-flashing lights, the object being to illuminate the clouds with sudden beams of light. In Section XIII. are given some memoranda for consideration in estimating the expenses of first cost and maintenance for lighthouses illuminated by gas. Section XIV. consists of a table showing the duration of fog at lighthouse and light-vessel stations on the English coasts, compiled from four years' records. Section XV. is a summarised journal of the lights shown each night during the year of the experiments.

It is stated that in order to make adequate provision for medical education in Japan, the Government intends dividing the country into six medical divisions, and to establish a medical college in each, in which the future surgeons and physicians will be trained.

On the 20th ult. Prof. Terrien de Lacouperie delivered the first of a series of lectures at University College, Gower Street, on the Science of Language and its recent progress, in connection with the languages of Indo-China. These languages, the lecturer said, are a new field of research in comparative philology which may lead to the reconsideration of several vital problems in the science of language. They offer a more satisfactory solution of these problems, and one more in accordance with the known facts of language past and present, but their influence has hitherto been injurious to the progress of linguistic science. The classification of languages into monosyllabic, agglutinative, and inflectional, is, he said, now recognised to be inadequate, and was based on a hypothesis of a primitive monosyllabic stage in the history of human speech which has never existed. The languages of Thibet, Burmah, Pegu, Siam, Annam, China, are generally called monosyllabic, and are still erroneously supposed by many to be living illustrations of the imaginary primitive language of monosyllabic roots. Such monosyllabism does not and never did exist. There are, the Professor said, three sorts of monosyllabism only—one of decay, one of writing, and one of elocution. It is to the last that the tongues of South-Eastern Asia belong, while the monosyllabism of English belongs to that of decay. The languages of the Far East, according to Prof. Lacouperie, belong to two great stocks—the Turanian and Himalayan—besides a residuum of Negrito and Papuan dialects. Turanian is represented by the great Kuenlunic branch, including (*a*) the Chinese family, (*b*) Tibeto-Burman group, (*c*) Yao-Karen group, (*d*) Dravidian family. Himalayan includes two great branches: (1) Indian, for the Kolarian languages, &c.; (2) Indo-Pacific, with four divisions—(*a*) Mōn-Taic, subdivided into two families—(1) Mōn-Annam, (2) Tai Shan—(*b*) Malayan, (*c*) Polynesian, (*d*) Micronesian. The second lecture, on the formation, evolution, and influence of Chinese, will be delivered on the 17th instant.

At a recent meeting of the Manchester Literary and Philosophical Society the special thanks of the Society were offered to Mr. Henry Wilde for the great liberality recently displayed by him in connection with the changes recently made in the building belonging to the Society, and in which it holds its meetings. When it was determined that new libraries should be erected to accommodate the rapidly increasing number of the Society's books, Mr. Wilde contributed the sum of 500*l.* to the building fund. The difference between the elegance of the new rooms and the dilapidated condition of the old ones offended Mr. Wilde's eye, and he resolved that he would, at his own expense, undertake their renovation. This he has now done at an additional cost to himself of 1100*l.* But the contribution of that money is only a part of what Mr. Wilde has done. He has personally superintended all the details of the work, rarely missing a day, during the last three months, in devoting several hours to that purpose. The results obtained evince at once the taste Mr. Wilde has displayed in regulating the style and character of the decorations.

We learn from a communication in *Naturen* that apatite has been found by Herr Enoksen, within the last few months, in certain parts of Norway where its presence had not previously been detected. The importance of this discovery to local industry is all the greater, owing to the fact that the Bamle beds, which have hitherto been the principal source from which this valuable mineral has been derived, are in the hands of a French company, which purchased them some years ago for 350,000 kroner, and still monopolises the trade. The demand for the mineral is, moreover, very considerable in Norway, one Norwegian factory, the chemical works of Stavanger, taking from the Company about 1000 tons annually, at a cost of 100 kroner per ton. According to the well-known geologist, Herr Hans Reusch, there is every reason to expect that apatite will be found with tolerable frequency in Norway when working engineers have learnt to distinguish it from the numerous valueless minerals, to which its variability of colour gives it some resemblance—for the geological formation in which it has now for the first time been detected near Stavanger, is not of uncommon occurrence in Norway. The little island of Hille, lying about five miles to the north-east of Stavanger, where Herr Enoksen has been so fortunate as to find true apatite, exhibits no products of eruption, but has extensive deposits of mica schist, largely intermixed with hornblende, and finely granulated gneiss. Here apatite is found near titanic iron in isolated masses, varying in size from a man's head to that of a nut. It occurs in various parts of the island, but its true character was not detected till Herr Enoksen showed that a piece of a stone not uncommon in the Hille schists, which had been sent to him as a scapolite, was in reality a fragment of genuine apatite. This unexpected discovery has given great impetus to the further search for this valuable mineral, which, as we learn from recent reports, has also been found in the hornblende schists of the Egersund.

An attempt has been recently made by Herr Liznar, of the Austrian Meteorological Society, to determine the daily course of cloudiness over different parts of the earth's surface. In most places there are two maxima and two minima in the day. He distinguishes four types, viz.:—(1) A maximum about midday, a minimum in the evening; this occurs, *e.g.* at Madrid (the maximum in summer becomes as late as 4 p.m.). (2) A maximum in the morning, and a minimum at midday; this is found at Los Angeles on the plateau of the Rocky Mountains. (3) Two maxima and two minima: the chief maximum in the morning, and the chief minimum in the evening; this type being met with in Vienna in winter and autumn, and in Bombay. (4) Two maxima and minima, but the chief maximum about midday and the chief minimum in the evening; this is the case at Vienna in summer and spring. The greatest amplitude of cloudiness appears at the stations on the Rocky Mountains plateaux; the sky being sometimes quite covered with clouds in the morning, and quite clear a few hours later. It is curious that the Sherman Station has a cloudiness exactly opposite in its course to that of Los Angeles. This meteorological element perhaps deserves more consideration than it has hitherto received.

A CORRESPONDENT of the *North China Herald* calls attention to a strange instance of Chinese belief and practice with regard to the human soul, which lately came under his notice. Lying awake at 3 a.m. he heard in the street close to his house two strange answering voices. Evidently two persons were engaged in this weird dramatic performance, one representing a departing soul, the other acting as the friends and relatives deprecating the departure. The first actor gave a low, prolonged cry, which was answered by a loud and earnest "Come, come." After a pause, the cry and the answering call were repeated; this went on for about ten minutes, when suddenly the inarticulate cry ceased. The second actor, in an agony of distress at the departure into the unseen of the soul he had been entreating to stay, shouted loudly in a voice, which he no doubt hoped would reach to the confines of the spirit world, "Return, return—come," at the same time calling by name. Then there was another pause, presently the low cry was heard as at a distance. "Come, come," eagerly responded the actor; and now the cry and the answer followed one another more rapidly till the cry seemed close to the caller, and in a smothered chorus as of welcome, the performance, which was probably directed by a Taoist necromancer, ceased. It is described as being strangely impressive in the stillness of the night, notwithstanding the grotesqueness of the superstition; but of course it was not known whether there was actual death in this case, within twelve hours of which the Chinese call for the soul to return, or whether it was only a case of serious illness, fainting, or collapse. This peculiar custom, it appears, varies in different parts of China. Up the Yangtsze it is usual for two women to perform the office. When a man dies suddenly the women walk through the streets, one calling out the name of the deceased, and the other responding "I am coming," the idea being to prevail on the wandering spirit of the deceased to return to its material abode, which, it is presumed, it has temporarily abandoned.

A NEW course of lectures has been established at the Collège de France on the mechanical theory of heat, magnetism, and electricity. The course will be given by M. Bouty.

ON October 22, at about 6 p.m., a slight shock of earthquake was felt at Ramsjö, in Sweden. It went from east to west, and lasted only a few seconds.

A LARGE consignment of Chinese and Japanese fish has lately reached this country, including the variegated goldfish, the nigger goldfish, the veil or fantail, the fringetail, and the nymphi. Some specimens have been on view at the Inventions Exhibition Aquarium, as well as some Russian loach and Hungarian beardfish. A large conger eel weighing 30 lbs., which had been in the tank for a long period, has just died.

MR. JOSEPH D. REDDING, a California Fish Commissioner, writes to Prof. Baird stating that he has invited investigation into the question of the devastation caused by sea-lions in the bays and seas of San Francisco, where they abound in very large numbers. They are very voracious, and it is alleged that they destroy hundreds of thousands of pounds of edible fish daily; whilst fishermen declare that their business is rapidly declining in consequence. Mr. Redding intends to present an exhaustive report to the California Legislature and to the United States Fish Commission.

THE observations that are to be undertaken by the National Fish Culture Association with a view to discovering the effect of certain influences upon marine fishes will be commenced this month. The stations from which observations will be made in the first instance are the Seven-Stones, the Royal Sovereign, and the Outer Dowsing. Besides these, other localities will be visited from time to time by observers appointed for the purpose, who will make the most complete investigations as to surface and bottom temperatures of the sea, the density and transparency of the water, the temperature of the air, &c. The question as to the declension in the yield of certain fisheries and the development of others will form the subject of inquiry, as will also the question of restoring depleted fishing-grounds to their former fertility.

A SOCIETY for popularising the use of scientific methods has been established in France under the name of the Topographical Society. It held its festive meeting on November 8 in the large hall of the Sorbonne; M. Ferdinand de Lesseps was in the chair.

WE understand that Messrs. Macmillan and Co. will shortly publish a book on Elementary Algebra, by Mr. Charles Smith, the author of well known and popular treatises on Conic Sections and Solid Geometry. After the severe remarks made by Prof. Chrystal at the last meeting of the British Association on the teaching of elementary algebra, a new work on this subject will be looked for with more than usual interest.

THE Belgian Technical Railway Commission has pronounced in favour of experiments on a large scale with steel railway sleepers. It is announced that the first trial will be made on 60 kilometres of line.

MR. ERIC STUART BRUCE has been carrying on experiments at Chatham for the English Government, with a view to the adoption of his system of military signalling. The official trial of his invention took place on October 17. To test the signalling apparatus the balloon was sent up four or five miles from Chatham and allowed to ascend 500 feet, when a series of sentences were flashed by the Morse system. The officers of the Royal Engineers who were deputed to inspect the apparatus have pronounced the experiments "eminently satisfactory." It has been suggested that this translucent balloon may be utilised for other military operations besides signalling—such as for a "point light," for concentrating forces by night; and owing to the wide area which is illuminated by the balloon, it has been proposed to use it for lighting working parties.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. Montague C. Clark; a Gannet (*Sula bassana*), British, presented by Mr. H. Archer; a Tawny Owl (*Syrnium aluco*), British, presented by Mr. J. Hillier; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mr. C. A. O. Marsham; a Squirrel Monkey (*Chrysothrix sciurea* ♀) from Guiana, a Ruffed Lemur (*Lemur varius* ♂) from Madagascar, a Macaque Monkey (*Macacus cynomolgus* ♀) from India, a Capercaillie (*Tetrao urogallus* ♂) from Norway, deposited; a Brazilian Tree Porcupine (*Sphingurus prehensilis*), a Naked-throated Bell-bird (*Chasmorhynchus nudicollis*) from Brazil, two Blue-winged Teal (*Querquedula cyanoptera*) from South America, five Lesser Snow Geese (*Chen albatus*) from Alaska, purchased; five Golden-bellied Beaver Rats (*Hydromys chrysogaster*) from Australia, received in exchange.

OUR ASTRONOMICAL COLUMN

THE ROTATION PERIOD OF MARS.—The seventh volume of the *Annals* of the Leiden Observatory contains a very thorough and painstaking investigation by Prof. Bakhuyzen of the rotation period of the planet Mars. In previous determinations one of two courses has usually been adopted, either to compare drawings of Huygens or Hooke with the most recent observations attainable, or to discuss some modern series which seemed to promise to compensate for its restricted range by its greater accuracy. Prof. Bakhuyzen has, however, endeavoured to utilise the entire mass of observations at his disposal, so as to avoid the sources of error to which the other methods are liable, and he possesses a great advantage over earlier investigators, in having access not only to the numerous observations made in 1877 and 1879, but also to the great series of more than 200 drawings which Schroeter had prepared for his projected "Areographischen Beiträge," and which, becoming the property of the University of Leiden in 1876, was edited and published by Prof. Bakhuyzen in 1881. Prof. Bakhuyzen, in the reduction of these drawings, has adopted provisionally Schiaparelli's position for the pole of Mars—R.A. 317° 46'·0, Dec. 53° 25'·4, mean equinox of 1833·0—and Proctor's rotation-period—24h. 37m. 22·74s.—and deduces corrections to these elements from a comparison of the results obtained by reducing the various observations at his command with them. His first step is, from a discussion of the drawings of Kaiser, Lockyer, Lord Rosse, and Dawes, made during the oppositions of 1862 and 1864, to obtain the time of transit on January 1, 1863, of his adopted prime meridian over the Martial meridian which passes through the earth's north pole, choosing as his prime meridian the one which lies 2° to the east of the centre of Mädler's point *a*, corresponding almost exactly to Schiaparelli's *Fastigium Aryn*, or to Proctor's *Dawes Forked Bay*, he finds the time of transit over the meridian passing through the north pole of the earth on January 1, 1863, to be 20h. 27·0m. ± 4·0m, Berlin M.T. The areographic longitude of the centre of the *Oculus*, the conspicuous circular spot, called by Green the *Terby Sea*, and by Schiaparelli *Lacus Solis*, will be, with this prime meridian, 90·87°. The second section contains the determination of the areographic longitudes of ten of the most conspicuous and easily identified markings on the surface of Mars as inferred by means of the above elements from the drawings of various observers from the time of Hooke and Huygens up to 1879. For the last-named year only Schiaparelli's observations are used, but for 1877 there is an abundant supply, there being available, besides the observations of Schiaparelli, the drawings of Lohse, Green, Dreyer, and Niesten. Beer and Mädler's drawings afford material for 1830, Herschel and Schroeter give a very full series from 1777 to 1803; and Huygens and Hooke supply a few drawings from 1659 to 1683, from which the longitude of Mädler's *f*, the *Kaiser* or *Hourglass Sea*, Schiaparelli's *Syrtis Major*, can be inferred. These longitudes are discussed in the third section, and a corrected rotation period is obtained of 24h. 37m. 22·66s ± 0·0132s., a value exceedingly close to the mean of the best previous determinations, which are as follows:—

	h. m. s.
Kaiser, 1864	24 37 22·62
Kaiser, 1873	·591
Schmidt, 1873	·57
Proctor, 1868	·735

Proctor's value is clearly too large, a comparison of the mean longitudes obtained for the *Kaiser Sea* with his period showing a steady decrease for successive oppositions; the only observations which stand conspicuously out from the rest being those of Hooke, upon which he had based his determination. There can be no doubt that Prof. Bakhuyzen's value is a distinct improvement upon the earlier ones, and that its uncertainty lies only in the second place of the decimals. A table for computing the time of transit of the prime meridian over that meridian of Mars which passes through the earth's north pole, completes the memoir.

Prof. Bakhuyzen supplies also a short note as to changes on the surface of Mars. The most conspicuous of all the markings on the planet's surface has always been the *Kaiser Sea*; but the drawings of Schroeter and Herschel, as Dr. Terby has already pointed out, exhibit a second marking near it, nearly as conspicuous, and very similar in shape and size. There can be no doubt that the only modern representative of this spot is *Huggins Inlet*, Schiaparelli's *Cyclopum*, a narrow streak, by no means easily observed, and now entirely unlike the *Kaiser Sea* in shape. Prof. Bakhuyzen also considers that there is sufficient evidence for thinking that Schroeter on several occasions observed Schiaparelli's *Læstrygonum*—one of the most difficult objects on the planet—which could scarcely have been the case had it not been much more conspicuous than it has been of late years. These changes, Prof. Bakhuyzen thinks, lend a high degree of probability to the theory that certain districts of Mars are covered by liquid.

THE SPECTRUM OF THE GREAT NEBULA IN ANDROMEDA.—Mr. O. T. Sherman, assistant at Yale College Observatory, reports in *Science* (vol. vi. Nos. 138 and 141) the discovery of three bright lines in the spectrum of this nebula. Of these the most refrangible corresponds to $H\beta$, and the wave-lengths of the other two are given as 5312·5 and 5594·0. It is suggested that the second of these lines is the well-known coronal line 1474 K, and that the third is one of the feebler coronal lines which Prof. Young observed in the 1869 eclipse, viz. the one at 1250 ± of Kirchhoff's scale. The observation, if confirmed, will go far to settle the disputed question as to whether the *Nova* is really or only apparently connected with the nebula, for two bright lines, of which one is probably 1474 K, have been observed in the spectrum of the former at the Royal Observatory, Greenwich.

THE WEDGE PHOTOMETER.—Dr. Wilsing in the *Astronomische Nachrichten*, No. 2680, criticises at considerable length several points with regard to Prof. Pritchard's use of the wedge photometer at the Oxford Observatory. Dr. Wilsing considers that Prof. Pritchard's investigations as to the figure of the wedge and its selective absorption leave nothing to be desired, but that the state of our knowledge of the physiological side of the question is still very incomplete. Experiments which Dr. Wilsing has made with two wedges of his own have convinced him that the variations in the sensibility of the eye are neither slight nor unimportant, and that they occasion discordances in the observations considerably greater than Prof. Pritchard is inclined to admit. Dr. Wilsing also finds that comparisons of differently coloured stars give results not directly comparable with eye estimations. He objects to the use of the method of limiting apertures for the determination of the value of the wedge constant, and points out that the influence of the intensity of the background affects Prof. Pritchard's magnitudes of the fainter stars very perceptibly. Despite all these drawbacks, however, he regards the wedge photometer as a useful addition to our equipment.

Mr. Chandler, who must at Harvard College enjoy special facilities for making himself well acquainted with the working of different forms of photometers, has recently expressed his preference for Argelander's method. There can, however, be no doubt but that the labours of Profs. Pritchard and Pickering have greatly advanced our knowledge of the comparative brightnesses of the northern stars.

PHOTOGRAPHING THE CORONA IN FULL SUNSHINE.—Mr. W. H. Pickering, of Harvard College, made a series of attempts during the partial eclipse of last March 16, to obtain a photograph of the corona. In this he was quite unsuccessful, for, though his plates showed several corona-like markings, they were clearly not due to the true corona, as they were found in front of the moon as well as on the sun's limb. From this Mr. Pickering was evidently led to conclude that the results which Dr. Huggins had obtained were probably of a similar character, and he expressed as much in a letter to *Science*. Dr. Huggins in reply pointed out that Mr. Pickering's method was faulty and was calculated to produce such false images. The latter, therefore, somewhat modified his apparatus, without, however, altering the two points which Dr. Huggins considered most erroneous—viz. the use of an object-glass instead of a reflector, and the placing his drop-slit close in front of the object-glass instead of in its primary focus. The result has been that he has obtained photographs free from false coronæ, but showing no real ones. At the same time he has made experiments which convince him that to produce a perceptible image of a coronal rift it is necessary to be able to discriminate between degrees of illumination which do not differ from each other by more than one-tenth the intrinsic brilliancy of the full moon. He considers that the eye is more able to detect small differences of light than a photograph is, and states that the moon cannot be photographed in full daylight, even though it may be easily seen. His investigations also lead him to think that even in the clearest weather the atmospheric illumination is 300 times as bright as it should be for it to be possible to obtain any image of the corona. To these points Dr. Huggins has replied in the *Observatory* for November. Dr. Huggins states that he has had no difficulty at all in photographing the moon in full sunshine, and that the observations of Prof. Langley and others of Mercury and Venus, which have been seen as black disks before they reach the sun, proves that the corona must have a sensible brightness as compared with the atmospheric illumination.

He also points out that Mr. Pickering fails to obtain any trace on his photographs even of the defects of his own instrument. Dr. Huggins declines further discussion, preferring to wait the result of the work now being carried on by Mr. Ray Woods at the Cape Observatory. Mr. Pickering replies in *Science* for October 23, admitting the possibility of photographing the moon in full sunshine, but contending that these very photographs of the moon supply an additional proof of his opinion that the light of the atmosphere near the sun is more than 300 times too intense for it to be possible to obtain a photograph of the corona, since the sky light near the sun was fifty times as bright as that near the moon, and coronal photographs, to be of any use, should be able to record differences of illumination of only one-tenth the brightness of the full moon.

He explains the visibility of Venus and Mercury as being caused by the refraction of the sun's light through their atmospheres, the black disk being thus surrounded by a narrow luminous ring.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *NOVEMBER* 15-21

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 15

Sun rises, 7h. 21m.; souths, 11h. 44m. 48·4s.; sets, 16h. 9m.; decl. on meridian, 18° 37′ S.: Sidereal Time at Sunset, 19h. 49m.

Moon (one day after First Quarter) rises, 13h. 18m.; souths, 18h. 37m.; sets, 0h. 3m.*; decl. on meridian, 8° 43′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury	9 6	12 54	16 42	24 8 S.
Venus	11 28	15 2	18 36	25 59 S.
Mars	23 40*	6 46	13 52	12 2 N.
Jupiter	2 14	8 23	14 32	1 5 N.
Saturn	18 48*	2 56	11 4	22 20 N.

* Indicates that the rising is that of the preceding and the setting that of the following day.

The Occultations of Stars and Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

GEOGRAPHICAL NOTES

The last number of the *Izvestia* of the Russian Geographical Society (xxi. 3) contains a variety of interesting papers. M. Ivanoff describes some Turkestan antiquities: namely, the Akhyr-tash, situated at the foot of the Alexander ridge, twenty-seven miles from Aulie-ata, one of the grandest buildings of antiquity, which covers nearly 20,900 square yards, and must have been some projected immense temple or palace; it was built from immense stones, weighing about one ton each, and brought from Tash-tube. M. Ivanoff gives for the first time a plan and a detailed description of the ruins of this immense building. Stone idols on the Issyk-kul, as also a burial-ground on the shores of the same lake, are described and represented by drawings. The whole is a most valuable contribution M. Trusman's paper on Finnish elements in the Gdov district of St. Petersburg will be welcome to Russian archæologists. Capt. Gedeonoff gives a list of forty-three places in the Trans-caspian region, whose positions have been determined by means of astronomical observations, as also their heights, determined by barometrical measurements. We notice the following: Khiva (house of Mat-murat), 41° 23′ 0″·1 N. lat., 60° 22′ 18″·9 E. long., 351 feet above the sea-level; Merv (Koushut-khan-kala), 37° 35′ 37″·6 N. lat., 61° 50′ 27″·9 E. long., 565 feet; and Tchardjui, 39° 1′ 33″·8 N. lat., 63° 36′ 12″·9 E. long., 433 feet. M. Konshin's paper on the Sary-kamysh lake basin and the western basin deserves more than a short notice, as it sums up the latest researches in this region, and presents the whole question as to the bed of the Amu-daria in quite a new light. A report on cartographical work in Russia in 1884 will be summed up under a separate head, as also two letters from Col. Prjevalsky and M. Potanin. Finally, the same issue contains two most valuable maps, by Gen. Tillo. One of them, on a larger scale, gives the lines of equal magnetic intensity, full and horizontal only, for Russia in Europe, reduced to the year 1880. On this map all places where observations have been made, as also where anomalies have been observed, are marked. Two other maps, on a smaller scale, give the lines of equal secular variation, both of the horizontal and of the total magnetical intensity. All three have explanations in German. These maps thus complete the remarkable work on "Earth-Magnetism in Russia," undertaken a few years since by M. Tillo, and already mentioned in Nature.

The last news from M. Potanin's expedition is embodied in a letter, dated San-chuan, January 25, and published in the last issue of the St. Petersburg *Izvestia* (xxi. 3). Leaving San-chuan on November 14, M. Potanin followed the right bank of the Hoang-ho up to He-cheu. The same red sandstones and conglomerates, covered with loess, were met with; the ridge which separates the Hoang-ho from the Tao-ho, intersected by deep ravines, is all covered with cornfields and villages; the soil abounding with moisture, villages are situated as high as 2000 feet above the bottom of the valleys. Crossing the Tao-ho and next the Da-sya-ho, the little half-ruined town of He-cheu was reached. The Da-sya-ho River is formed by the junction of three rivers—the Huishu, the Tumun, and the Leu-guan—situated 70 li above the town. This last river was followed by the expedition, and its source was reached after a two days' march. Its valley is wide and well-peopled in its lower half, the upper one being a mere gorge thickly covered with brush-wood, and quite unpeopled. Crossing a ridge at the sources of the Leu-guan and its tributary, Urunka, the broad valley of the Tchitai was next reached. Its banks consist also of sandstones and conglomerates, and it is thickly peopled with Salars, its upper part being occupied by Tanguts. Descending this valley, a two days' march brought the expedition to the confluence of the Tchitai with the Yellow River; and another two days' march brought them to San-chuan. On this stretch the Yellow River flows in a narrow gorge between steep crags of the red sand-stones and conglomerates, and the road ascends these crags or follows their slope on narrow wooden balconies, or by flights of steps cut in the hard rock. The right bank of the river is inhabited by Salars. They have maintained their Turkish language in great purity. The men wear a Chinese dress, but the women wear broad trousers, and a broad overcoat with sleeves, and a pointed bonnet which covers the upper part of the back. They are all Mussulmans, but their mosques are of Chinese architecture, and are decorated with dragons, lions, and tigers. Above its gorge the Yellow River flows through a depression seven miles long and less than two miles wide, which has received the name of San-tchuan, or Gurban-tala, and is peopled exclusively by Mongolian Shirongols. Their central village is Ni-ja. The Shirongols seem to belong to the same stem as that described by M. Prjevalsky under the name of Dalda in the vicinity of Kuku-nor. Both are called Tu-jen by the Chinese. If this supposition is correct, they would appear to occupy the territory from the longitude of He-cheu to that of Gan-cheu. They speak Mongolian, with an addition of Chinese words, but have some words of their own which must be remains of the language they have spoken in their former territory, the Urdus. Their dress is Chinese, but the women have maintained the same trousers as the Salars, and their houses have much likeness with those of these last. They live on agriculture and gardening. All the religions of the region are met with among them. Around He-cheu they are all Mussulmans; but families having several male children send one of them to a Lamaite monastery so as not to divide their land-holdings too greatly, and so a class of Buddhist Lamas has arisen. Those who have received Chinese instruction follow the teachings of Confucius, while the remainder go indifferently to Buddhist or Chinese temples, and many have Shamanist divinities. As to M. Berezovsky, he has left the expedition and has taken another route, *viâ* Hoy-syan; he proposes to rejoin MM. Potanin and Skassi on their way to the south.

THE expedition which is reported to have been massacred in New Guinea was sent out by the Geographical Society of Australasia, founded in May 1883. The commander, Capt. Henry Charles Everill, had been selected from a number of candidates, and his staff included a naturalist, a surgeon, two sub-leaders, one on land and the other on sea, a photographer, three natural history collectors, a surveyor, an engineer, and a "general utility" volunteer. Very full instructions were drawn out for the expedition, while considerable discretion was left to the leader to adapt his operations to circumstances. The instructions included directions not only for surveying work, but for observations on the natives, on zoology, botany, and geology, with directions for the collection and preservation of specimens. The expedition was to enter the Aird River, which is probably only an east arm of the Fly River. As a matter of fact, a telegram of September 22 announced the arrival of the *Bonito* (the vessel in which the expedition sailed from Sydney) in the Fly River. It was to penetrate as far as possible into the interior. The Australasian Society contributed 500*l*. to the expedition of Mr. H. O. Forbes, who, according to latest news, was at Port Moresby preparing to penetrate into the interior. Happily the report of the massacre is discredited by the British resident on Thursday Island.

THE Geographical Society of Lisbon passed a resolution at its last meeting asking the Portuguese Government to make a money grant by way of remuneration to the explorers MM. Capello and Ivens, and to pay the cost of publishing not less than 5000 copies of the account of their journey. It was also resolved to address every commercial association throughout the country pointing out the necessity of establishing a company or society for the purpose of investigating colonial markets hitherto imperfectly known, but of which MM. Capello and Ivens are showing the importance.

AT the last meeting of the Paris Society of Commercial Geography on the 20th ult., the Burmese Envoy being present, M. Bran de Saint Pol Lias described his recent journeys in Indo-China, which appear not to have extended far beyond Saigon, Cambodia, and the delta of the Red River. Indeed, travel even in these comparatively frequented parts of the peninsula must have been difficult when the traveller was there, for the greater part of Tonquin and Cambodia was in rebellion at the time of his visit.

THE *Bulletin* (2^e trimestre, 1885) of the Paris Geographical Society, just published, contains a long report on the labours of the society, and on the progress of the geographical sciences, by M. Maunoir, the secretary. The work is, as usual, well and thoroughly done. The only other paper in the number is a description of the regions of Algeria traversed by the meridian of Paris, by Commander Derrien. This is accompanied by a map, and describes in succession, and with great detail, their orography, hydrography, geology, military roads, meteorology, military and administrative divisions, and also discusses the origin of the tribes of the Jebel Amour.

THE Geographical Society of Tokio appears to be steadily pursuing its work. The recent numbers of its *Journal*, which we have before us, show much activity in regions around Japan. Amongst the papers in the sixth volume we notice the following:—The five races of the Chinese Empire, and their ancient progress, by Mr. Otori; the interior of Northern Corea, by Mr. Kaizu; travels in Siam; notes on Thibet (compiled from European sources); Formosa under the Chinese; Manchuria: recent events in Annam; travels in South-eastern Russia; the salt-tax in China; colonisation in Saghalien (a review); Formosa during the Dutch occupation; historical notes on the relations between Russia and China; notes on the aboriginal language of Formosa, with a considerable vocabulary; Candahar and the Lower Cabul Valley, with a sketch map; the mines of Central Japan, with a map, and various other minor communications. The first number of the tenth volume contains a paper by Mr. Akamatsu on the origin and condition of the Chinese emigrants to the Philippines, based apparently on the writings of Prof. Blumentritt on the subject; and one on the longitude of Japan, by Mr. Arai, the head of the meteorological bureau. The *Journal* is printed in Japanese, but a short table of contents is appended in English.

THE leading paper in the current number (Heft 3, Band viii.) of the *Deutsche Geographische Blätter*, the organ of the Geographical Society of Bremen, is one by Leonard Steineger, describing a voyage around Behring Island, off the coast of Kamchatka, in the autumn of 1882. It describes at some length the incidents of the voyage, the capabilities of the island, &c. The writer visited and describes the ruins of the hut in which Behring and his companions wintered 141 years previously, and where the traveller himself died, and was buried. Dr. von Steiner compiles from Mr. Im Thurn, an account of the Indians of Guiana. The usual geographical news concludes the number.

MR. SCOTT, of the Indian Survey Department, recently delivered a lecture at Calcutta on the transfrontier surveys of India, in which he pointed out that 20,000 square miles on the immediate north-western frontier needed exploration. Here lie the Kafila routes into Afghanistan, which he much regretted had not been used for the advance into Afghanistan instead of the hot and thirsty Bolan Pass. He suggested that the rules against British officers crossing the frontier should be relaxed, and that they should be permitted to accept invitations, with a guarantee of safety, by native officers to their homes across the border.

THE death of Col. Obrigado, of the Argentine Army, on September 22 at Buenos Ayres is announced. In recent years he had made many scientific explorations on the coasts and in the interior of Patagonia. He traversed the forests in the basins of the Negro, Limay, and Nanquen rivers, which had never been explored before; and several places in these regions now bear his name. His death was due to ill-health, caused by his journeys in Patagonia.

THE last issue of the *Mittheilungen* of the Geographical Society of Vienna contains two papers on the Carolines; one by Prof. Blumentritt describing the historical relations of Spain to the archipelago. He makes more interesting quotations from books used in Spanish schools, in which the Carolines are mentioned amongst the colonies of Spain, and the usual elementary school-book information is given about them. The secretary to the Society also gives a map of the group, with much geographical and other information respecting them. Herr Jülg concludes his paper on the erosive action of the sea, and the usual current geographical information brings the number (Band xxviii., No. 10) to a conclusion.

THE SCOTTISH METEOROLOGICAL SOCIETY

AT a meeting of the Directors of the Ben Nevis Observatory held on October 30, it was intimated that during the summer Prof. Ewing, of Dundee, had visited the Observatory to make arrangements for the observations on earthquakes and earth movements which it had been resolved to carry on there. Prof. Vernon Harcourt and Mr. Harold Dickson, both of Oxford, also spent some time at the Observatory conducting experiments and observations on the intensity of light in flames, it being necessary, in connection with the important practical question of a satisfactory determination of the light-giving qualities of coal gas supplied to the public, to make experiments on such a situation as Ben Nevis, where barometric pressure is low. Mr. H. N. Dickson resided two months at the Observatory, being chiefly engaged in carrying out, under the superintendence of Prof. Tait and Mr. Buchan, a valuable series of observations and experiments on the methods of observing the temperature and humidity of the air. For this purpose the season was a singularly suitable one, on account of the extremes of temperatures and humidities the weather presented during the summer on the Ben. As regards the humidity, where there were of course abundant opportunities of studying the behaviour of the instruments in an atmosphere completely saturated through a wide range of temperature, many cases occurred of excessive and protracted dryness of the atmosphere. On one occasion, in September, no deposition of dew took place on

Prof. Chrystal's condensation hygrometer, though its temperature was lowered to 9°·0. These quite exceptional arid states of the air on Ben Nevis during the past summer are of the greatest interest, especially in their relations to the unprecedentedly severe early frosts which were so destructive to the potato and cereal crops over extensive breadths of the country during September. It was reported that since the middle of August subscriptions to the amount of about 300*l.* had been already received from the original subscribers, and it was resolved to make the claims of the Observatory more widely known. At the same meeting the Council resolved that the discussion of the observations of the temperature of the sea round Scotland be undertaken by the Scottish Marine Station at Granton chiefly with the view of constructing isothermal maps of the sea for each month round the Scottish coasts. The Secretary reported that he had during the summer inspected twenty-six of the Society's stations. The Duke of Buccleuch, and Messrs. Donald Beith, W.S.; Robert Irvine of Royston; B. N. Peach, Geological Survey; and John Horn, also of the Geological Survey, were elected members of the Society.

ON THE INTELLIGENCE OF THE DOG[1]

THE man and the dog have lived together in more or less intimate association for many thousands of years, and yet it must be confessed that they know comparatively little of one another. That the dog is a loyal, true, and affectionate friend must be gratefully admitted, but when we come to consider the psychical nature of the animal, the limits of our knowledge are almost immediately reached. I have elsewhere suggested that this arises very much from the fact that hitherto we have tried to teach animals, rather than to learn from them—to convey our ideas to them, rather than to devise any language or code of signals by means of which they might communicate theirs to us. The former may be more important from a utilitarian point of view, though even this is questionable, but psychologically it is far less interesting. Under these circumstances it occurred to me whether some such system as that followed with deaf mutes, and especially by Dr. Howe with Laura Bridgman, might not prove very instructive if adapted to the case of dogs. I have tried this in a small way with a black poodle named "Van." I took two pieces of cardboard about 10 inches by 3, and on one of them printed in large letters the word "food," leaving the other blank. I then placed two cards over two saucers, and in the one under the "food" card put a little bread and milk, which "Van," after having his attention called to the card, was allowed to eat. This was repeated over and over again till he had had enough. In about ten days he began to distinguish between the two cards. I then put them on the floor and made him bring them to me, which he did readily enough. When he brought the plain card I simply threw it back, while, when he brought the food card, I gave him a piece of bread, and in about a month he had pretty well learned to realise the difference. I then had some other cards printed with the words "out," "tea," "bone," "water," spelt phonetically, so as not to trouble him by our intricate spelling, and a certain number also with words to which I did not intend him to attach any significance, such as "nought," "plain," "ball," &c. "Van" soon learned that bringing a card was a request, and soon learned to distinguish between the plain and printed cards; it took him longer to realise the difference between words, but he gradually got to recognise several, such as "food," "out," "bone," "tea," &c. If he was asked whether he would like to go out for a walk, he would joyfully pick up the "out" card, choosing it from several others, and bring it to me, or run with it in evident triumph to the door. I need hardly say that the cards were not always put in the same places. They were varied quite indiscriminately and in a great variety of positions. Nor could the dog recognise them by scent. They were all alike, and all continually handled by us. Still I did not trust to that alone, but had a number printed for each word. When, for instance, he brought a card with "food" on it, we did not put down the same identical card, but another bearing the same word, when he had brought that a third, then a fourth, and so on. For a single meal, therefore, eighteen or twenty cards would be used, so that he evidently is not guided by scent. No one who has seen him look down a row of cards and pick up the one he wanted could, I think, doubt that in bringing a card he feels he is making a request, and that he can not only distinguish one card from another, but also associate the word and the object. This is, of course, only a beginning, but it is, I venture to think, suggestive, and might be carried further, though the limited wants and aspirations of the animal constitute a great difficulty. My wife has a very beautiful and charming collie, "Patience," to which we are much attached. This dog was often in the room when "Van" brought the food card, and was rewarded with a piece of bread. She must have seen this thousands of times, and she begged in the usual manner, but never once did it occur to her to bring a card. She did not touch or indeed even take the slightest notice of them. I then tried the following experiment:—I prepared six cards about 10 inches by three, and coloured in pairs—two yellow, two blue, and two orange. I put three of them on the floor, and then holding up one of the others, endeavoured to teach "Van" to bring me the duplicate. That is to say, that if the blue was held up, he should fetch the corresponding colour from the floor; if yellow, he should fetch the yellow, and so on. When he brought the wrong card he was made to drop it, and return for another till he brought the right one, when he was rewarded with a little food. The lessons were generally given by my assistant, Miss Wendland, and lasted half an hour, during which time he brought the right card on an average about twenty-five times. I certainly thought that he would soon have grasped what was expected of him. But no. We continued the lessons for nearly three months, but as a few days were missed, we may say for ten weeks, and yet at the end of the time I cannot say that "Van" appeared to have the least idea of what was expected of him. It seemed a matter of pure accident which card he brought. There is, I believe, no reason to doubt that dogs can distinguish colours; but as it was just possible that "Van" might be colour blind, we then repeated the same experiment, only substituting for the coloured cards others marked respectively I., II., and III. This we continued for another three months, or, say, allowing for intermissions, ten weeks, but to my surprise entirely without success. I was rather disappointed at this, as, if it had succeeded, the plan would have opened out many interesting lines of inquiry. Still in such a case one ought not to wish for one result more than another, as of course the object of all such experiments is merely to elicit the truth, and our result in the present case, though negative, is very interesting. I do not, however, regard it as by any means conclusive, and should be glad to see it repeated. If the result proved to be the same, it would certainly imply very little power of combining even extremely simple ideas. I then endeavoured to get some insight into the arithmetical condition of the dog's mind. On this subject I have been able to find but little in any of the standard works on the intelligence of animals. Considering, however, the very limited powers of savage men in this respect—that no Australian language, for instance, contains numerals even up to four, no Australian being able to count his own fingers even on one hand—we cannot be surprised if other animals have made but little progress. Still, it is surprising that so little attention should have been directed to this subject. Leroy, who, though he expresses the opinion that "the nature of the soul of animals is unimportant," was an excellent observer, mentions a case in which a man was anxious to shoot a crow. "To deceive this suspicious bird, the plan was hit upon of sending two men to the watch-house, one of whom passed on, while the other remained; but the crow counted and kept her distance. The next day three went, and again she perceived that only two retired. In fine, it was found necessary to send five or six men to the watch-house to put her out in her calculation. The crow, thinking that this number of men had passed by, lost no time in returning." From this he inferred that crows could count up to four. Lichtenberg mentions a nightingale which was said to count up to three. Every day he gave it three mealworms, one at a time; when it had finished one it returned for another, but after the third it knew that the feast was over. I do not find that any of the recent writers on the intelligence of animals, either Buchner, or Peitz, or Romanes, in either of his books, give any additional evidence on this part of the subject. There are, however, various scattered notices. For instance, there is an amusing and suggestive remark in Mr. Galton's interesting "Narrative of an Explorer in Tropical South Africa." After describing the Damara's weakness in calculations, he says:—"Once while I watched a Damara floundering hopelessly in a calculation on one side of me, I observed 'Dinah,' my spaniel, equally embarrassed on the other; she was overlooking half a dozen of her new-born puppies,

[1] Abstract of paper by Sir John Lubbock, Bart., M.P., F.R.S., read at the Aberdeen meeting of the British Association.

which had been removed two or three times from her, and her anxiety was excessive, as she tried to find out if they were all present, or if any were still missing. She kept puzzling and running her eyes over them backwards and forwards, but could not satisfy herself. She evidently had a vague notion of counting, but the figure was too large for her brain. Taking the two as they stood, dog and Damara, the comparison reflected no great honour on the man." But even if "Dinah" had been clear on this subject, it might be said that she knew each puppy personally, as collies are said to know sheep. The same remark applies generally to animals and their young. Swans, for instance, are said to know directly if one of their cygnets is missing, but it is probable that they know each young bird individually. This explanation applies with less force to the case of eggs. According to my bird-nesting recollections, which I have refreshed by more recent experience, if a nest contains four eggs, one may safely be taken; but if two are removed, the bird generally deserts. Here, then, it would seem as if we had some reason for supposing that there is sufficient intelligence to distinguish three from four. An interesting consideration arises with reference to the number of the victims allotted to each cell by the solitary wasps. One species of Ammophila considers one large caterpillar of *Noctua segetum* enough; one species of Eumenes supplies its young with 5 victims; another 10, 15, and even up to 24. The number appears to be constant in each species. How does the insect know when her task is fulfilled? Not by the cell being filled, for if some be removed she does not replace them. When she has brought her complement she considers her task accomplished, whether the victims are still there or not. How, then, does she know when she has made up the number 24? Perhaps it will be said that each species feels some mysterious and innate tendency to provide a certain number of victims. This would, under no circumstances, be any explanation; but it is not in accordance with the facts. In the genus Eumenes the males are much smaller than the females. Now, in the hive-bees, humble-bees, wasps, and other insects, where such a difference occurs, but where the young are directly fed, it is of course obvious that the quantity can be proportioned to the appetite of the grub. But in insects with the habits of Eumenes and Ammophila the case is different, because the food is stored up once for all. Now, it is evident that if a female grub was supplied with only food enough for a male she would starve to death; while if a male grub were given enough for a female it would have too much. No such waste, however, occurs. In some mysterious manner the mother knows whether the egg will produce a male or female grub, and apportions the quantity of food accordingly. She does not change the species or size of her prey; but if the egg is male she supplies 5; if female, 10 victims. Does she count? Certainly this seems very like a commencement of arithmetic. At the same time it would be very desirable to have additional evidence how far the number is really constant. Considering how much has been written on instinct, it seems surprising that so little attention has been directed to this part of the subject. One would fancy that there ought to be no great difficulty in determining how far an animal could count; and, whether, for instance, it could realise some very simple sum, such as that two and two make four. But when we come to consider how this is to be done the problem ceases to appear so simple. We tried our dogs by putting a a piece of bread before them and preventing them from touching it until we had counted seven. To prevent ourselves from unintentionally giving any indication we used a metronome (the instrument used for giving time when practising the pianoforte), and to make the beats more evident we attached a slender rod to the pendulum. It certainly seemed as if our dogs knew when the moment of permission had arrived; but their movement of taking the bread was scarcely so definite as to place the matter beyond a doubt. Moreover, dogs are so very quick in seizing any indication given them, even unintentionally, that, on the whole, the attempt was not satisfactory to my mind. I was the more discouraged from continuing the experiment in this manner by an account Mr. Huggins gave me of a very intelligent dog belonging to him. A number of cards were placed on the ground, numbered respectively 1, 2, 3, and so on up to 10. A question is then asked: the square root of 9 or 16, or such a sum as $6 \times 52 - 3$. Mr. Huggins pointed consecutively to the cards, and the dog barked when he came to the right one. Now Mr. Huggins did not consciously give the dog any sign, yet so quick was the dog in seizing the slightest indication, that he was able to give the correct answer. This observation seems to me of great interest in connection with the so-called "thought-reading." No one, I suppose, will imagine that there was in this case any "thought-reading" in the sense in which this word is used by Mr. Bishop and others. Evidently "Kepler" seized upon the slight indications unintentionally given by Mr. Huggins. The observation, however, shows the great difficulty of the subject. I have ventured to bring this question before the Section partly because I shall be so much obliged if any lady or gentleman present will favour me with any suggestions; and partly in hope of inducing others with more leisure and opportunity to carry on similar observations, which I cannot but think must lead to interesting results.

Dr. Flower remarked that the crowded state of the room was sufficient evidence of the interest taken in whatever of the numerous subjects Sir John Lubbock cared to enlighten them upon. Sir John Lubbock was unable to make his dog count seven, but a dog at a place where he (Dr. Flower) was living recently certainly knew when the seventh day of the week came. The dog, most eager on every other day of the week to go for a walk, betrayed no desire to go on Sunday when his master took up his hat and stick to go to church. It struck him that the method which Sir John had adopted was the only one by which they could put themselves in relation to the minds of these animals—namely, the method of kindness and encouragement. Too many had tried to do these things by a system of intimidation and cruelty, but he did not think they could really know what dogs could do, and bring out their faculties, without patience and perseverance, encouragement, and uniform kindness.

Miss Catherine Rae explained the way in which she got a dog, within three weeks, to ring a bell. She began by letting "Tiny" smell the bone of a mutton chop, and then tied the bone to the string of the bell. At first "Tiny" was in a great tremor, but, by taking her very kindly and stroking her, she found that she could induce her to pull at the bone and so to ring the bell. After that she tied a small piece of wood to the string, but the dog would not pull it. At last she pulled her gently back till the bell rang, and in this way, in the short course of three weeks, with not more than one or two lessons a day, the dog would go and ring the bell by being told—"'Tiny,' go and ring the bell." At the end of three weeks she gave an evening party, and during the evening they were all electrified by the sudden and violent ringing of the bell. "Tiny" had been neglected to be indulged with any tit-bit, and had taken this means of receiving attention.

Miss Becker said, with regard to the experiments with the crow mentioned by Sir John, to show that it could not count beyond three, that something of the same kind might happen with a person. Place three eggs upon the table, and any one could say there were three; but if there were twelve he would require to count them to be sure of the number.

Mr. C. C. Walker gave an instance of a dog being taught politics. He belonged to a family where Liberal politics prevailed, and the dog showed his sympathy by growling fearfully when the name of "Dizzy" was mentioned, and at the name of his master giving expression to unbounded delight. Similar demonstrations at public meetings, he added, were often made with as little intelligence as those of the dog.

Some other remarks were made, one gentleman suggesting that as long as the dog was ignorant of the words "one," "two," "three," "four," he would not be able to count or get beyond the mere perception of magnitude.

Sir John Lubbock thought with reference to the question of Sunday that there were so many slight indications in the household generally to distinguish the day that he had never been able to regard that as proof of a dog counting, although it was a very interesting fact in itself. As regards several of the other cases they were clever tricks, but his suggestion was to operate in exactly the opposite direction; not to teach the dog, but to enable the dog to communicate with us.

NITROGEN IN THE SOIL

EACH of the elements required for building up the frame of animals and plants is of equal importance from a scientific standpoint, but in agriculture the various salts and substances which yield food for crops or for cattle must necessarily be valued according to their cost. There are exceptions to this rule, no doubt. Gypsum is a cheap manure, but it has sometimes doubled the clover crop, and kainit salts are comparatively cheap. Yet for some crops, especially potatoes, in cases of a deficient supply of potash in the soil, they have sometimes proved invaluable. In general, however, cost and efficiency are closely associated, and as plants and animals are almost alike in their chemical composition the same rule as to the value of their constituents holds good. You may purchase starch and the carbo-hydrates at a much lower rate than the nitrogenous substances in food. Turnips, bread fruit, and bananas, consisting chiefly of carbo-hydrates, are sold by their respective growers at a very different and much lower price than milk or peas, which are rich in albuminous elements. In every form nitrogen is always comparatively costly. The albumen in eggs, the fibrine in cereals, the casein in milk, and the legumin in peas and beans, all owe their importance and cost to this particular element, which is the source of force and vigour, of the labour of the hardest-worked cattle and men, of lean meat and muscle.

Considering the limited supply of nitrogen and the cost of obtaining it, it is not surprising that it should often be present in cultivated soils in quantities insufficient for a full crop, and that the land, when dressed with salts of nitrogen, should answer to their touch as a horse does to the spur. In the Rothamsted experiments the unmanured field yielded for years about fourteen bushels, or half a crop, till a dressing of nitrogen was given to it, when immediately the crop was doubled, nitrogen having been, as it often is in clay soils, the one thing needful to a full crop. Sir John Lawes has been sometimes asked by American farmers how to restore the exhausted fertility of their fields, so that the land, yielding fourteen bushels per acre, which is about the average of corn-exporting countries, might be induced to return twice as much. It is fortunate for English farmers that Sir John can only send advice into the far West ; he cannot send nitrogen.

Some years ago the agricultural community was flattered by the immediate prospect of a never failing supply of nitrogen. The marvels of chemistry and analysis had recently been unfolded by the writings of Sir H. Davy and Baron Liebig, and the efficacy of guano had accustomed farmers to the new method of supplying nitrogen to the land in concentrated forms and from sources outside the farmyard. Then came the promise of obtaining nitrogen from the atmosphere. The agricultural classes are rarely much moved by anything but bad weather and falling prices, and the chemists had explained to them that the nitrogen of the atmosphere, existing as it does in a free state mixed with oxygen, was not available for agricultural purposes. If it could be induced, they were told, to enter into combination with hydrogen the result would be ammonia, an invaluable manure. This was understood by farmers, and a great sensation was occasioned among them when Mr. Nasmyth, the inventor of the steam hammer, proposed to control the supply of the most costly of plant constituents by knocking it out of the atmosphere. It is easy to see that if Mr. Nasmyth had succeeded in knocking nitrogen and hydrogen into combination at a moderate cost, a revolution in the price of manures and of food must have speedily occurred.

But as the plan failed and as plants still "live and move and have their being" in the midst of an element which they cannot feed on, it was certainly surprising to learn lately that nitrogenous manures had ceased to produce their accustomed effect. The phenomenon occurred at the Duke of Bedford's experimental farm at Woburn, where, according to official statements, the yield of wheat manured by the dung of animals fed on maize proved as abundant as the crop which followed from manure produced by the feeding of cotton cake, which enriches the excreta with far more nitrogen than that produced by feeding maize.

The Woburn experiments were instituted by the Royal Agricultural Society and were placed under the management of its chemist, the late Dr. Voelcker, for the purpose of testing the value of manure obtained by the consumption of different kinds of food and to compare the effects of such manures with those of artificial manures. It is evident that in such a comparison the land to which the various fertilisers were applied should have been of similar quality. But there are other disturbing causes which may vitiate experiments of this kind, and these were not at first generally recognised. The mistake occurred in some rotation experiments in which the manure derived from cotton cake containing about 40 per cent. of nitrogenous constituents was compared in its results with that obtained from maize, a cereal containing only 10 per cent. of albuminoids. The results of these experiments were known to the agricultural community before the report of Dr. John Voelcker, who has succeeded his late father as chemist to the Royal Agricultural Society, had been made, and much surprise was expressed that at the close of the second rotation the cotton cake had not shown any decided superiority over the maize. It has been recently explained in an official report on the "Objects, Plan, and Results of the Woburn Experiments," that this was "probably due to the large amount of unexhausted manure in the land." Before commencing experiments, therefore, on the comparative value of manures the land should be exhausted by repeated scourging crops, as at Rothamsted, where in some cases the deep-rooting Bokara clover has been grown for the special purpose of reducing the fertility of the soil to *nil*.

It has long since been established that nitrogen is neither absorbed by plants from the atmosphere nor conveyed into the soil to any appreciable extent in any way except by the direct application of manure : still there are some crops which collect nitrogen and leave the surface-soil richer than before. Red clover is usually grown as a preparation for wheat, and although clover hay must necessarily withdraw a great deal of plant-food from the soil, it does not prove exhaustive in practice because the deep and fleshy roots of the plant collect nitrogen from the subsoil and, in their decay, supply it to the growing wheat-crop. Under such circumstances a strong nitrogenous manure may not be required, and may perhaps prove less desirable than a weak manure containing less nitrogen. Enough has been said to show that the field experiments which are now becoming popular, and which are being instituted at many "stations" throughout the country, will require great care and the supervision of managers who possess a competent knowledge both of "practice and science."

H. E.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

LONDON.—In accordance with resolutions passed at the extraordinary meeting of the Convocation of the University of London held on July 28 last, an adjourned extraordinary meeting of the House was held on Tuesday week in the University Building, Burlington Gardens, which was very numerously attended. The Chairman of Convocation (Mr. F. J. Wood, LL.D.) presided, and in his opening address explained his ruling that under the said resolutions the business pending before the former meeting might now be proceeded with, and invited the House to resume the debate accordingly. At the time of the adjournment the House had a motion before it, made by Lord Justice Fry, for the reception and adoption of the report of the special committee appointed to consider the project of the "Association for Promoting a Teaching University for London." To this motion an amendment had been moved by Mr. J. W. Bone, seconded by Mr. Philip Magnus, omitting all the words in the original motion after the word "received." At Tuesday's meeting leave was given to Lord Justice Fry to accept the amendment, which thus became a substantive motion, to which his Lordship, however, immediately proposed to add "And that the House now consider what amendments, if any, ought to be made in the said scheme, and that such amendments, if any, be by way of instruction to a committee of revision." For Lord Justice Fry's motion 76 only voted against 122 who negatived it. Ultimately after a three hours' sitting the debate was adjourned to Tuesday, December 8.

ALDERMAN SIR R. N. FOWLER, BART., M.P., has consented to present the City and Guilds of London Institute's Scholarships, Prizes, and Certificates at a meeting to be held on Wednesday evening, December 9, at the Salters' Hall, St. Swithin's Lane, E.C. The Right Hon. the Lord Mayor will preside.

SCIENTIFIC SERIALS

Mittheilungen der Naturforschenden Gesellschaft in Bern, Nos. 1064 to 1091, 1883-4 (three parts).—Contributions to the doctrine of metal-poisoning, by J. Marti.—Terrestrial and fresh-water mollusca collected in the neighbourhood of Berne and Onterlacken, by G. Regelsperger.—An automatically-acting thermograph, by G. Hasler.—Influence of sexual excitation on the composition of cow's milk, by F. Schaffer.—Further paper on the animal world in the pile-dwellings of the Lake of Bienne, by Th. Studer.—On a parasite in the intestine of the horse, by M. Flesch.—On the nature of odorous matters and the causes of smell, by A. Valentin.—Mathematical considerations on the structure of bees' cells, by A. Jonquière.—On the inhibitory mechanism of the heart, by A. Glause.—On the separation of manganese and nickel by means of ozone, by V. Schwarzenbach.—On determinate integrals, by J. H. Graf.

SOCIETIES AND ACADEMIES

London

Zoological Society, November 3.—Prof. W. H. Flower, F.R.S., President, in the chair.—Mr. Sclater exhibited the skull of a Tapir received by the Society in May, 1878, which was then described as *Tapirus roulini*, but which had since been found, upon anatomical examination, to be merely a dark variety of *Tapirus americanus*.—A letter was read from Mr. J. Caldwell, C.M.Z.S., of Port Louis, Mauritius, announcing the finding of a new deposit of dodo-bones in a small cavern in the south-west part of the island.—An extract was read from a letter addressed to the Secretary by Dr. F. H. Bauer, C.M.Z.S., of Buitenzorg, Java, containing some notes on the Flying Lizard (*Ptychozoon homalocephalum*) of that island.—Prof. Bell exhibited and made remarks on a fine specimen of the Decapod Crustacean, *Alpheus megacheles*, obtained by Mr. Spencer at Herm, Channel Islands.—Mr. Martin Jacoby communicated the second portion of his paper on the Phytophagous Coleoptera of Japan obtained by Mr. George Lewis during his second journey, 1880–81. The present part treated of the Halticinæ and Galerucinæ of Mr. Lewis's collection.—Mr. A. G. Butler read a paper containing an account of two collections of Lepidotera recently received from Somali Land. Mr. Butler considered that the Lepidopterous fauna of Somali Land was essentially Arabian in character.—Mr. L. R. Lydekker, F.Z.S., described a last upper molar of a Mastodon, which had been obtained by Mr. A. H. Everett, C.M.Z.S., in Borneo, and referred it to a small race of *M. latidens*, previously known only from the Pliocene Siwaliks of India and Burmah. The specimen was of much interest, as increasing our knowledge of the eastern range of the Siwalik mammals.—Mr. W. T. Blanford, F.R.S., read a monograph of the genus *Paradoxurus*. After a critical examination of a large series of specimens Mr. Blanford came to the conclusion that it would be necessary to reduce the numerous so-called species of this genus to about ten well-marked forms.—Mr. W. T. Blanford, on behalf of Mr. J. A. Murray, read a paper containing the description of a new species of *Mus* from Sind, proposed to be called *Mus gleadowi*.—Mr. F. E. Beddard, F.Z.S., read an account of the specific characters and structure of some New Zealand earthworms of the genus *Acanthodrilus*.

Paris

Academy of Sciences, November 2.—M. Bouley, President, in the chair.—The Perpetual Secretary announced the death of M. Joly, Corresponding Member of the Section for Anatomy and Zoology, who died at Toulouse on October 17, 1885.—Remarks on the subject of M. Hirn's recent experiments on the velocity of gases with a view to testing the truth of the kinetic theory of gases, by M. Faye. The author infers from the results of these experiments that the kinetic hypothesis will have to be reconsidered, if not absolutely rejected. The limit which it imposes on the velocity of gases under certain conditions of temperature and pressure is shown to be imaginary.—Fresh researches on the origin of the glandular nervous fibres and of the vaso-dilator nervous fibres which form part of the chord of the tympanum and of the glosso-pharyngian nerve, by M. Vulpian.—Remarks on M. H. Filhol's new work entitled "Recherches zoologiques, botaniques, et géologiques faites à l'île de Campbell et en Nouvelle-Zelande," by M. Alph. Milne-Edwards. The researches embodied in this work tend to show that since the Chalk or beginning of the Tertiary epoch Campbell Island can have formed no part of New Zealand or of any other Australasian region.—Solution of a question of indeterminate analysis constituting a fundamental principle in the theory of the Cremona transformations, by M. de Jonquières.—Experimental researches on the temperature observed in the mother at the moment of delivery and of the child at birth: comparison of these two temperatures, by M. Bonnal.—On the attenuation of the virus of ovine variola, by M. P. Pourquier. From his researches, continued for a period of seven or eight years on the principles established by M. Pasteur, the author concludes that it is possible to attenuate this virus, to transform it into a true vaccine, and thus avoid the serious losse hitherto incurred by inoculating sheep against the disease.—On the Cremona transformations in a plane of n order, by M. G. B. Guccia.—On the decomposition of quadratic forms, by M. Benoit.—Note on the theory of M. Helmholtz respecting the preservation of solar heat, by M. Ph. Gilbert.—Note on the doubly-refracted dispersion of quartz, by M. J. Macé de Lépinay.—On the theoric distribution of heat over the surface of the globe, by M. A. Angot.—Combination of the nitrate of silver with the alkaline nitrates (nitrates of potassa, rubidium, ammoniac, soda, and lithine), by M. A. Ditté.—On the anhydrous chloride and silicate of cerium, by M. P. Didier. Having already determined the action of hydrosulphuric acid on the anhydrous chloride of cerium, the author now communicates a process for preparing this substance, and describes some other compounds obtained by its means by the dry process.—Note on the Asteriadæ collected during the *Talisman* expedition, by M. Edm. Perrier. As many as fifty-four species, represented by nearly 200 specimens, were obtained on this occasion, some fished up from depths exceeding 4000 metres.—On the respiration of leaves in the dark: carbonic acid retained by them, second note, by MM. Dehérain and Maquenne.—Note on artificial earthy specular iron, by M. Stan. Meunier.—On the zymotic properties of charbon and septicemic blood, by M. A. Sanson.—On the transmission of virulent glanders to the pig, by MM. Cadéac and Malet.—Treatment of mildew in the vine by means of the sulphate of copper, by M. A. Müntz.—The sulphate of lye-ashes and its employment against animal and vegetable parasitic diseases, by M. Duponchel.—Account of a remarkable meteoric phenomenon observed at Pondicherry on June 13, 1885, by M. C. André.

LOOMIS'S "CONTRIBUTIONS TO METEOROLOGY"

Contributions to Meteorology. By Elias Loomis, LL.D., Professor of Natural Philosophy and Astronomy in Yale College, &c. Revised Edition. (New Haven, Conn., U.S., 1885.)

IT is now fifty years since Prof. Loomis's attention was directed to the study of meteorology, his interest in the subject having been awakened by Redfield's investigations respecting the phenomena and laws of storms. During the first forty years his principal writings were elaborate discussions of the great storm which occurred in America in December 1836, and an equally remarkable storm which occurred in Europe shortly after the American storm, and an account of another United States storm in February 1842, which in a part of its course was accompanied by a tornado of unusual violence. The chief outcome of these investigations was a new method of charting observations, now so familiar to all the world in our weather maps, and the demonstration of the capital fact in meteorology, that in storms the movement of the wind is spirally inwards, circulating from right to left about the centre of the cyclone.

The generally imperfect character of the barometric observations for a long time precluded all attempts at any satisfactory investigation of the storms and weather of the United States; and it was not till 1871, when the Signal Service was organised, with its uniform methods of observation and reliable barometers, that the data required for the investigation was supplied. When two years' observations had accumulated, Prof. Loomis resumed his inquiries, and from July 1874 a series of papers by him, entitled "Contributions to Meteorology" have appeared from time to time in the *American Journal of Science*. A large number of these we have noticed in NATURE as they appeared. As the subjects investigated were taken up without any regard to systematic order, and as a change of views has necessarily come about as the investigations proceeded, Prof. Loomis has wisely resolved to reduce them to a more systematic form and incorporate into the revised work the results of observations now available, not only from the United States, but also from Europe and other parts of the world. The present pamphlet contains the first chapter of this revision, and the subject dealt with is the areas of low atmospheric pressure, their form and magnitude, and the direction and velocity of their movements.

As regards the forms of areas of low pressures, or cyclones as they are conveniently termed, the greatest and least diameters of all the cyclones represented on the Weather Maps of the Signal Service during a period of three years were actually measured, with the result that the average ratio of the longest diameter to the shortest was 1·94. In 53 per cent. of the whole number of cases the ratio was 1·5; in 33 per cent. 2; in 11 per cent. 3; and in 3 per cent. 4. Similarly the Atlantic storms, as delineated on Hoffmeyer's charts for a period of three years, have been examined, and the measurements show that the ratio of the longest diameter of the cyclones to the shortest is 1·70; and that while in 54 per cent. of the whole number of cases the ratio was 1·5, in 17 per cent. it was 2, and in 1 per cent. 3—thus showing a marked deficiency of very elongated low pressure areas over the Atlantic Ocean as compared with the United States.

Observations show that the longest diameter of cyclones may be turned in any azimuth. In the States it is most frequently directed towards a point somewhat East of North, the point towards which the longest diameter is most frequently directed being N. 36° E. The average direction is sensibly the same for the cyclones of the Mississippi Valley and for those of the Atlantic coast. Over the Atlantic Ocean the direction of the longest diameters are more equally distributed in azimuth than they are in the United States, but the point towards which the longest diameter is most frequently directed is N. 35° E., which corresponds almost exactly with the direction found for the United States.

The cyclones of the tropics frequently exhibit a violence greater than is ever known in the storms of the middle latitudes, but their geographical extent is comparatively small. The inclination of the winds inwards upon the centre is shown to be more strongly marked in tropical cyclones than in most storms of the middle latitudes. From an examination of the weather maps of the Signal Service it is found that in the United States a low pressure area, with only one system of cyclonic winds, frequently has a diameter of 1600 English miles, and Hoffmeyer's charts show that cyclones over the Atlantic have frequently diameters of 2000 English miles. Widespread areas of low barometer, having several centres of cyclonic action, may have a diameter of 6000 English miles or may even form a belt extending nearly, if not entirely, round the globe between the parallels of 40° and 50° N. lat. On the other hand, tropical cyclones are often only 500 miles in diameter, and are occasionally of still less dimensions.

When low pressure areas are very much elongated, two or three cyclonic centres are frequently included within the same area of low pressure. Though these cyclonic centres are occasionally of equal depth, yet they are more generally of very unequal depth and intensity. The weather charts of the morning of March 9, 1876, showed a very large area of low pressure overspreading Europe and the Atlantic Ocean, having a principal centre of low pressure in the north of Scotland, around which violent winds prevailed, rising to 12 on Beaufort's scale, with very steep gradients on the western side of the cyclone. About the same time, and within the same widespread low pressure area, there were four other cyclones, with their centres at St. Petersburg, South Russia, south coasts of the Black Sea, and over the Caspian Sea, respectively.

As an illustration of one of the more extensive areas of low pressure, Prof. Loomis adduces the great barometric depression of June 7, 1882, as shown on the International Weather Map of the Signal Service of that day. This area of low pressure covered the whole of Asia, apparently extending from the equator to a considerable distance beyond the North Pole; it covered the whole of Europe with the exception of a small portion of its southern margin, and also the northern part of the Atlantic Ocean and stretched across the central portion of North America to the Pacific Ocean: thus extending through 320 degrees of longitude. The principal low centre, 29·200 inches, was north of the Caspian Sea; a second low centre, 29·400 inches, was over the northern part of India; a third low centre, 29·600 inches, over the Gulf of St. Lawrence; a fourth low centre, 29·800 inches, over China; a fifth low centre, 29·800 inches, north-east of Japan; and if every part of this large portion of the earth's surface had been sufficiently represented by observing stations several other subordinate low centres would doubtless have been exhibited. On the other hand, a centre of high pressure, 30·400 inches, was found over the Atlantic Ocean; a second, 30·200 inches, over the south-eastern part of the United States; and a third, over the eastern part of the Pacific near latitude 30° N. The area of high pressure formed a belt closely following the parallels of 30°—35° and extending through at least 240 degrees of longitude, but interrupted by the Asiatic Continent.

We drew attention five years ago to the all-important bearings of these areas of high and low pressure on the weather in all the regions of the globe over which anomalously high and low barometers at any time prevail (NATURE, vols. xxi., xxii. and xxiii.). But the importance of this department of meteorology is much enhanced when it is considered that it is through a careful record of the appearance and disappearance in different regions of the globe of these cyclonic and anti-cyclonic areas and an investigation of the causes determining their form, position, and intensity from time to time that we may hope to reach the solution of the problem of the weather. In prosecuting this large inquiry, the results of Prof. Loomis's careful measurements of meteorological phenomena, as detailed in the revised edition of his "Contributions" now before us, form one of the best guides we at present possess.

Direction of Movement of Areas of Low Pressure.—Areas of low pressure, or cyclones, seldom remain stationary in the same position for many hours. The centre of low pressure generally changes its position steadily from hour to hour, and everywhere there is observed a marked uniformity in the direction of this movement. Prof. Loomis gives several charts showing the progressive movement of cyclones in different parts of the world, including one showing nearly all the different storm tracts delineated on the International Weather Maps of the United States Signal Service for a period of more than four years. Maury's Storm Charts are also brought under review. The lowest latitude reached by the centre of any cyclone, which has been distinctly traced, is 6° 1′ N., and there are only eight cases of cyclones whose paths have been traced to points south of lat. 10° N.

Observations indicate that, both in the Pacific and Atlantic, gales are of extremely rare occurrence within six degrees of the equator, and, when they do occur, the barometric depression is small, and the cyclonic character of the winds indistinctly marked. But in low latitudes, a little higher than six degrees, gales are more frequent over the Pacific than over the Atlantic Ocean.

Tropical storms which are found to pursue a westerly course are limited to two regions of the globe—viz. the Atlantic Ocean, but particularly its western portion, near the West India Islands, and the region south of the continent of Asia. As regards the Pacific, no cyclone has ever been observed, except near Asia or its outlying islands.

As regards the tracks of tropical cyclones in the neighbourhood of the West Indies, the teaching of the data represented on the International Charts is that nearly all the areas of low barometer which occur within the tropics and advance westwards, instead of following the ordinary course of the trade winds, advance in a direction somewhat north of west. Of these West Indian cyclones, 88 per cent occurred in August, September, and October, thus leaving only 12 per cent. for the other nine months of the year. On the other hand, of the Asiatic cyclones 52 per cent. occurred in September, October, and November, and 43 per cent. in April, May, and June, thus leaving only 5 per cent. for the other six months. There is, therefore, a marked seasonal difference as to the frequency of the tropical cyclones of the Atlantic as compared with the Pacific: in the Atlantic they are almost exclusively confined to the autumn, but in the Pacific they are nearly as frequent in spring as in autumn.

The average direction of the course of the Asiatic cyclones, while moving westward, is 38° north of west, which closely accords with that found for West Indian cyclones. But, as regards the onward progress of tropical cyclones, whilst Asiatic cyclones advance westwards at the average rate of 8 English miles per hour, the average velocity of West Indian cyclones is double that amount. Asiatic cyclones come around to a due north course about lat. 19°·8 N., but West Indian cyclones do not assume a due northerly course till, on the average of instances, lat. 30° N. is reached. In the Pacific the average course of cyclones, after turning eastward, was 35° E. of N., and their velocity was 9·8 miles, which is scarcely half of the velocity of the West Indian cyclones. These striking and vital differences between the tropical cyclones of the Atlantic and the Pacific will doubtless play no unimportant part in the development of the theory of the cyclone.

An examination of Prof. Loomis's chart of storm-tracks for the northern hemisphere, with wind charts indicating the prevailing direction of the wind, shows a remarkable correspondence between the two classes of facts. Examining the point more narrowly, Prof. Loomis finds that for the middle region of the Atlantic, near lat. 50°, the average direction of storm paths corresponds very closely with that of the average direction of the wind; but in the western part of the Atlantic the average course of storms is considerably more northerly than that of the wind, while in the eastern part it is more southerly. These results, which fairly accord with those derived from tropical storms, seem to indicate, in the opinion of the author, that in the middle latitudes of the northern hemisphere the direction of progress of storm-centres is not the same as that of the average wind, but is sensibly affected by some other causes; and that the results derived from observations in the China Sea indicate that one of the causes is the prevalent direction of the wind which immediately follows a storm. The subject is further prosecuted by an examination of the prevailing winds and storm-tracks during the three winter months for the ten winters ending 1882 of that portion of the United States between long. 90° W. and the Rocky Mountains. The result of this somewhat exhaustive comparison is similar to that derived from the observations on the Atlantic—there being observed no rigorous correspondence between the average direction of the movement of storm-centres and the prevailing wind; but that in some regions the average course of storm-centres is more northerly than that of the wind, and in some regions more southerly.

While in middle latitudes the generally progressive movement of cyclones is in an easterly direction, cyclonic areas are occasionally observed, both in Europe and America, advancing to westward. After a careful investigation of forty-one of the most decided cases which have occurred of these westerly movements of cyclones, it is considered that the following conclusions are warranted—viz. that the westerly movement of low-pressure centres is due to a fall of rain or snow, in most cases unusually great, in the region towards which the low centre advances; and the influence of one low-pressure area acting apparently as an attractive force upon another adjacent low-pressure area; to the influence exerted by two areas of high pressure, not far apart, by which a new movement is imparted to the air included between them, a new low centre being sometimes developed; or to the influence of a high pressure on the north-east side of a low-pressure area, when the gradients on the south-west side of the low area are slight, in which case the centre of the low-pressure area may be crowded towards the south-west.

Rate of Progress of Cyclones.—The rate of progress of the United States storms for thirteen years has been calculated, and the results arranged according to the months, and expressed in miles per hour. The average rate of progress for the year is 28·4 miles, rising to the maximum, 34·2 miles in February, and falling to the minimum, 22·6 miles, in August. As regards different years, the variation is also much greater in the winter than in the summer months. Thus, in November, 1878, the rate was 21·2 miles per hour, but in the same month of the following year it was 40·7 miles; and, on the other hand, in July, 1882, the rate was 19·8 miles, but in July, 1881, it was 26·6 miles—the difference between the extremes of November being thus 19·5 miles, and in July only 6·8 miles.

In Europe during the five years ending 1880 the mean annual rate of progress was 16·7 miles, rising to the maximum, 19·0 miles, in October, and falling to the minimum, 14·0 miles, in August. Hence the onward movement of storms in the United States is two-thirds greater than in Europe, the rate of excess for the United States over Europe being 1·9 in winter, and 1·5 in summer. On the mean of the year the average onward movement of storms is, in miles per hour, 28·4 for the United States, 18·0 for the middle latitudes of the Atlantic, 16·7 for Europe, 14·7 for the West Indies, and 8·5 for the Bay of Bengal and the China Sea.

Prof. Loomis is led to conclude that the general system of atmospheric circulation, consisting of the trades of equatorial regions and the westerly winds of the middle latitudes, is the primary cause which determines both the direction and velocity of the movement of storm centres; but as respects each individual storm, the determining cause is not so much the average system of atmospheric circulation, as the general movement of the atmosphere going on at the time, and in the vicinity of that particular storm. The influence of this general movement is, moreover, materially modified by a variety of causes, among which may be enumerated the rainfall, and the position of the region over which it falls with respect to the centre of the storm; the size and position of neighbouring areas of high and low pressure, the distribution of temperature, and the physical configuration and character of the surface.

In further prosecuting this important discussion, the time has perhaps now come for meteorologists to give more consideration and weight to the physical conditions of the cyclone, more particularly to the method of distribution of temperature and aqueous vapour within and in the more immediate neighbourhood of the cyclone. This point, which was so strongly dwelt on and urged by Dove, has for some time past been allowed to fall too much into the background. A cyclone is not merely a system of low pressure with winds all around blowing vorticosely inwards upon the centre; but it is further distinguished by this, that the atmosphere in front of its path is relatively warm and moist, and in the rear cold and dry. These features are seldom kept so steadily in view by meteorologists as they ought to be in the discussion of such questions as Prof. Loomis has here brought under review.

One outstanding difference of the storms of America and those of Europe is that nearly all of the American storms originate on the continent, not far from the Rocky Mountains, whereas the storms of Europe originate mostly on the ocean. It is not improbable that more than one of the important points of difference between these two classes of storms shown by Prof. Loomis have their explanation in the different conditions under which they have their origin.

OUR BOOK SHELF

A Treatise on the Calculus of Variations. By L. B. Carll, A.M. (London: Macmillan, 1885.)

A Text-Book on the Method of Least Squares. By Mansfield Merriman. (London: Macmillan, 1885.)

Both these works by American mathematicians have been, we believe, printed in America, and are now introduced to the attention of English students by Messrs. Macmillan. They are first-class representatives of the good work now being done in this field: we have (Nature, vol. xvi. p. 21, vol. xxvi. p. 59) already given account of other American mathematical publications.

Mr. Carll, on his title page, states that his treatise is "arranged with the purpose of introducing, as well as illustrating, its principles to the reader by means of problems, and designed to present in all important particulars, a complete view of the present state of the science." The subject is one which certainly has not engaged the time of our book-compilers, for which good and sufficient reasons might be assigned. In 1810, as Todhunter writes, a work was published by Woodhouse, which has obtained a high reputation for accuracy and clearness. That work was not followed by any systematic treatise in English until the year 1850, when Mr. Jellett brought out his valuable "Elementary Treatise on the Calculus of Variations," an octavo volume of 377 pages, with an introduction of 20 pages. In the later editions of Mr. Todhunter's integral calculus are given such portions of the subject as are generally read by students. The same writer's "History" and "Researches" should be in the hands of all who desire to get up this branch thoroughly. After the lapse of so long an interval as thirty-five years we are not surprised to find that Jellett's work is difficult of access to general readers, and on this ground, if on no other, we welcome the present attempt to bring the "Calculus" to the fore again. The author follows Airy and Todhunter in the view he takes of a variation, and Jellett and Strauch in the treatment of varying functions, but he has not neglected to give fairly full accounts of the conceptions and methods of other writers.

A good deal of the preface is taken up with details which might well be omitted should the work reach a second edition, as we hope it may.

There are in all five chapters (568 and xvii. pages) printed in good type and in excellent style.

Chapter i., maxima and minima of single integrals, involving one dependent variable is broken up into ten sections: Chapter ii., maxima and minima of single integrals involving two or more dependent variables in two sections: Chapter iii., maxima and minima of multiple integrals in six sections. Chapter iv., applications to determining the conditions which will render a function integral one or more times in two sections.

Chapter v. gives a historical sketch of the rise and progress of the calculus of variations founded upon Todhunter's "History," and closes with an account of the "Researches in the Calculus of Variations," referred to above.

We have nothing to say of Mr. Merriman's work in addition to what we have said already (NATURE, vol. xxx. p. 334): the works are identical, except in the title pages.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Italian Aid to Biological Research

THE Committee appointed by the Royal Academy of the Lincei in Rome at the request of H.E. the Minister of Naval Affairs, to see that the best possible use in the interests of science be made of the natural history specimens collected by officers of the Royal Italian Navy, wishes to make known to all students of biology that rich material for study, consisting of a certain number of plants and extensive collections of animals of nearly all classes, is at present deposited at the Zoological Station at Naples. This material has all been collected by the officers of the Royal Navy, principally by the *Vittor Pisani* in a recent voyage round the world, and by other Italian men-of-war in the Red Sea and the Ægean Sea. These collections have been preserved by the best and most modern methods, and can be used for histological and morphological researches, in accordance with the actual requirements of science, as well as for systematic and faunistic investigations. The Committee places this rich material at the disposal of the men of science of all countries who will ask to take part in its illustration, either to complete monographs in course, or for monographical works or for special research on any organic system of a given group.

The requests, on which the Committee will decide, are to be sent to Prof. Trinchese, University of Naples.

The Resting Position of Oysters

IN a letter from Mr. J. T. Cunningham in your impression of NATURE of October 22 (p. 597) it is sought to show that the oyster does not rest on its left but on its right valve. The evidence which appears to him conclusive on this question is "that the right flat valve is always quite clean, while the convex valve is covered with worm-tubes (*Stylea grossularia*) and Hydroids."

This observation is correct on the whole, but not decisive for the question under consideration. After reading Mr. Cunningham's letter I proceeded to examine 140 oysters in my collection of Schleswig oysters, and found only on a few right valves a worm (*Pomatoceros tricuspis*) or a Cirripede (*Balanus crenatus*), whereas on many *left* valves I distinguished sponges (*Halichondria panicea*), *Alcyonium digitatum*, Hydroids (*Sertularia argentea, Tubularia indivisa, Eadendrium rameum*), Bryozoa (*Alcyonidium gelatinosum*), *Balanus crenatus, Pomatoceros tricuspis*, or *Sabellaria anglica*. Of the 140 oysters examined 43 still bore on their shells the body on which as spawn they had reared themselves, namely pieces of oyster-shells, *Mytilus edulis, Mya arenaria, Mya truncata, Cardium edule*, or *Buccinum undatum*. All these adherent bodies were attached to the nucleus of the left valve, not one single piece to the nucleus of the right. And this is a circumstance decisive in the question raised by Mr. Cunningham. The places on the right valve, where living animals rest, did not stick close to fixed bodies, but the water flowed freely over them, thus admitting embryos to settle on them. The bottom of oyster banks is not a smooth surface, but is formed mainly of old oyster-shells on which many living oysters do not assuredly plant themselves closely and horizontally, but lie often obliquely. It is thus that Hydroids, Sponges, Alcyonium, and Alcyonidium, having settled on the right lower valve, are enabled to grow freely in the water and without let or hindrance develop to the length of four or five inches.

Kiel, October 31 KARL MÖBIUS

Universal Secular Weather Periods

I DO not want to pose as a statistical cycle-hunter, or to bolster up any mere apparent local periodicity of a certain meteorological element, but I wish to place before your readers the appended independent paragraphs from two journals, one on each side of the Atlantic, and to ask any unprejudiced person if we have not here some preliminary evidence (all the more valuable from its being so evidently incidental and unconscious) in favour of the march of certain secular weather areas, possibly connected with barometric waves, similar to those traced out by Messrs. Chambers and Pearson in India, across the Atlantic, from America to Europe.

I would not submit such slender evidence to criticism were it not that it concurs entirely with certain views put forward by myself in a recent paper in the Royal Meteorological Society's *Quarterly Journal*, on "The Height of the Neutral Plane of Pressure in India," and that I have long felt that the entire question demands attention both on scientific and economical grounds. Also both paragraphs include last year, thus bringing the apparent periodicity up to date.

Being at present fully engaged in two other branches of research, I am unable just now to take up this hopeful and important problem, but I would suggest that if we ever intend to forecast the *general character* of the weather of a season or year, which even in this country undergoes long periodic changes, during which it remains for weeks and months together of the same *type*, some such method as the following must be adopted:—

Annual and seasonal mean barometric charts must be constructed from records at principal stations in America, Europe, and Asia for the past fifty or sixty years, and from them barometric abnormals for each year, and for each season, must be calculated, and charted. An examination of these ought to throw great light on, if not to some extent solve, the question of the motion of the larger pressure areas which in turn guide and control the motion of the smaller diurnal systems. The work would, I admit, be one of some considerable magnitude, but surely it is one imperatively demanded in the interests of the science, besides being *a priori* likely to yield valuable results. It has long been a cherished idea of mine to endeavour to carry out the scheme myself, and it is only because I feel precluded from doing so at present by the pressure of other work that I throw out the suggestion for the benefit of any who feel disposed to take it up.

The paragraphs are as follows :—

Mr. Baldwin Latham, in a discussion which ensued upon the Report of the Committee on Decrease of Water Supply (*Quarterly Journal* Roy. Met. Soc., p. 223), said :—

"The records showed that there appeared to be a recurrence of low water every ten years. There was lower water in 1824 and in 1835; the period 1844–5 was low, especially when compared with the years immediately before and following; 1854 was remarkably low; also 1864–5, 1874–5, and now they come to the present low period of 1884–5.

"As to what was the cause of this marked periodicity it was very desirable to ascertain, and, having pointed it out, probably some light might be thrown on the subject."

The other is from the *American Meteorological Journal* under the heading "Cold Winters in Michigan," and the writer says :—

"It is interesting in this connection to notice that the local reports of extremely cold winters place them at intervals of between ten and eleven years. . . . The winter of 1842–3 is thus shown to have been extremely cold; also the winter of 1853–4; the winter of 1863–4 noted for its terribly cold new year; the winter of 1874–5, when the frost penetrated into the ground in Port Huron four to six feet, there being scarcely a thaw between January 1 and the middle of March; and, lastly, the winter of 1884–5, which beats the record for extreme cold during January and February."

I may add that before I had seen either of these paragraphs I had concluded from other sources that the years 1821–2–3–4, 1833–4, 1844–5, 1866–7, and 1875–7 were characterised by mild winters in Europe and unusual cold in Iceland and America, being preceded in most cases by drought during the summers; but of course this represents merely the result of a preliminary glance at some general records of noteworthy seasons.

November 9 E. DOUGLAS ARCHIBALD

Photography of the Corona

I HAVE been following with interest the communications which have been made from time to time to *Science* by Mr. W. H. Pickering regarding the photography of the corona in full sunshine. Whilst admiring the manner in which he has built up his theoretical objections to its possibility, I am forced to dissent from his deduction from the fact that the theory does not fit in with the results actually obtained during the eclipses observed in Egypt and the Caroline Islands. I have in my hands at present spectrum and other photographs of the corona made during the expeditions to those localities, and from them I gather he has evidently much underestimated the photographic brightness of the corona as compared with that of the sky. As I propose shortly to read a paper before the Royal Society on the subject, I cannot enter into details at the present moment. All I will say is that the comparative photographic intensity of both can be estimated with approximate exactness from the data I have by me.

I write this for insertion in your columns, as in your last issue you have a note regarding Mr. W. H. Pickering's communications on this subject. W. DE W. ABNEY

Permanence of Continents and Oceans

MANY naturalists are accustomed, in lecturing, to speak of the existing ocean basins as "permanent." Though this must to a large extent be a true statement, many geologists at all events must be perfectly aware that the former distribution of life requires that nearly all lands, however remote at present, must have been, perhaps more than once, in connection with each other. Tropical South America is perhaps the most isolated continental province now existing. I would ask these naturalists to explain how its species of tropical genera not peculiar to it got there, and how many of them came to be represented in Europe in Tertiary times.

That the lands are always chiefly centred about the same spots, and also the converse, would, I think, be an acceptable way of putting it; but that the Atlantic was never bridged except towards the Arctic and Antarctic circles, is a statement that is unwarrantable because contradicted by unimpeachable evidence. J. STARKIE GARDNER

History of Elasticity

IN order to estimate Poncelet's services to the theory of elasticity I am extremely desirous of examining certain works by him. These works are not to be found in the London or Cambridge Libraries, and the Paris booksellers to whom I have applied despair of being able to procure copies. It will hardly be possible for me to go to Metz to examine them before the publication of the first volume of the "History of the Mathematical Theories of Elasticity." Possibly some of your readers may know of the existence of accessible copies in this country. If so, I should esteem it a great favour if they would communicate with me at University College.

In 1827–29 Poncelet gave at Metz a "Cours de Mécanique Industrielle aux Artistes et Ouvriers Messins." In this "Cours" various important points of theoretical elasticity were considered for the first time.

It was published as follows :—

(*a*) Part I. Lithographed edition, Metz, 1827.

(*b*) Part II. First edition lithographed 1828; second edition lithographed 1831.

(*c*) Part III. Lithographed edition, 1831.

(*d*) Part I. First printed edition, Metz, 1829; second printed edition, Metz, 1831.

It is needful to remind your readers that there are numerous other works entitled "Mécanique Industrielle," by Poncelet, published at Liége, Paris, and Brussels, differing from each other, and entirely from the above. These I have examined, but they do not contain what I require. KARL PEARSON

The Heights of Clouds

In the very favourable notice of our "Mesures des Hauteurs et des Mouvements des Nuages," in NATURE of October 29 (p. 630), there exists a misunderstanding as to the probable errors of our measurements, which makes our observations seem much more inexact than they really are. I therefore ask your permission to correct it.

Mr. W. de W. A. says: "Perhaps one of the most easily-observed clouds is the cumulus, and we find from a table given that the *probable error of observation* is very considerable." But, in fact, what is there referred to as an error of observation is not such an error; it is the probable uncertainty ("incertitude probable") *depending on the variability of the phenomenon itself.*[1] This is expressly stated in the treatise. On p. 39 (that following the table quoted) there may be read: "L'incertitude calculée comprend ainsi et celle dépendant de la variation des hauteurs des nuages, et celle provenant des erreurs d'observation. Celle-ci est cependant assez petite par rapport à la première et à peu près constante pour les différentes heures du jour, comme on le trouvera en la calculant séparément à l'aide des erreurs moyennes *m*." That mean error *m* is just the *mean error of observation* in the height of a cloud, and in our "list of observations" we have given it for every observation, as well as the corresponding mean angular error of the observation. By calculating the probable error of an observation of cumulus by means of those values of mean errors we have found it to be 35 *metres* (instead of 748 metres, as Mr. W. de W. A. thinks it to be), and the probable error of the mean is found to be 3 metres (instead of 40 metres), the whole number of observations being 134.[2]

Thus the above assertion is fully justified, viz. that the errors of observation may be quite neglected when compared with the uncertainty depending upon the variability of the heights of the cumuli from one cloud to another. That variability is itself a phenomenon worthy of investigation, varying as it does according to the hour of the day and the barometrical state of the weather, and that is the reason for which we have calculated it. As to the mean angular error in observing a cloud, we have found it very often to be inferior to that obtained in observing the centre of the sun, and in all the better observations that error is fully comparable to the error in observing the sun, as may be seen from our treatise. This proves that, for such observations, the uncertainty of an identical point of cloud did not exist at all, the whole uncertainty depending on the unavoidable instrumental errors. Still it may be that the errors are

[1] For the figures in the table quoted represent simply the *probable difference* of an observation (of the mean found) from the *true* mean calculated by the method of least squares.

[2] For the higher clouds, as the pure cirri, this error was often very great indeed, but it was so because their distance was much too great when compared with our basis, the parallax obtained being not greater than 1° or 2°. This year (1885) the measurements are regularly pursued from the ends of a basis of 1302 metres, and we can now determine with great accuracy the height even of the most elevated cirri, as well as their horizontal and vertical velocities.

somewhat less in using a photographic theodolite than in using our instruments. But on the other hand our method enables us to observe the clouds even in twilight and moonlight, in rain and storm. Also, it is, no doubt, much cheaper than the photographic one. N. EKHOLM

Upsala, November 6

The Helm Wind

SOME years ago I passed a summer at Melmerby, which is about the best place for seeing the "helm," which is incorrectly described as affecting the Penrith valley (for, in fact, it never extends to Penrith) by your correspondent, M. Woeikoff.

Melmerby is at the foot of the Cross Fell range, and gets the "helm" with great violence. When an easterly wind comes on, the summit of Cross Fell becomes clouded; *it puts on its helm:* then from this a violent cold wind pours down the hillside (which is steep) and rises up again at no great distance. At Melmerby, and places similarly situated, there is clear sky, for the moisture in the sky is invisible, but further from the range it is precipitated where the current rises, and there is cloudy sky, without the strong wind. The phenomenon is, in fact, precisely that at Table Mountain, where the cloud on the crest is called the "table-cloth."

Judging from M. Woeikoff's description there seems to be a difference in the phenomena. Probably owing to the *gentle slopes* of the Varada chain the air does not seem to *rise again*, and there is no cloud-bank parallel to the chain. It would seem, too, that the wind extends to the *west*, unless there is a misprint. J. F. TENNANT

THE MODE OF ADMISSION INTO THE ROYAL SOCIETY

OUR contemporary *Science*, in the last number which has reached this country, makes some remarks concerning the admission of candidates into the Royal Society, against which, in the interests of truth and accuracy, it is our duty to protest, the more especially as it is also implied that the French system of canvassing those who are already Fellows of the Society is also adopted.

The statements actually made are (1) that there is an "actual competitive examination, on the result of which a certain number of successful candidates are annually chosen," and (2) "that the English method has the additional disadvantage that it does not secure the men whom it is most desirable to honour." We read also, "During the schoolboy period the distinction between different individuals is a distinction of learning, and an examination is not unfitted to discover the boy who deserves reward. But learning is not the quality which a State needs to make it great. Casaubons are not the kind of men who have built up English science. The qualities which ought to be encouraged, and which it should be a nation's delight to honour are qualities too subtle to be detected by a competitive examination."

For the benefit of our transatlantic brethren we may as well state the facts as we know them. For reasons into which we need not enter here, as they do not affect the question at issue, nearly forty years ago the Royal Society determined to limit the yearly admissions to fifteen; and to throw upon the Council the responsibility of selecting the fifteen who are to be nominated for election, a general meeting of the Society reserving to itself the right of confirming or rejecting such nomination. It may be instructive to remark that for thirty years that right has not been exercised.

The way in which the matter is worked is as follows:—The friends of a man, who are already in the Society, and who think he is entitled to the coveted distinction, prepare a statement of his services to science, in many cases without consulting him in any way. This paper thus prepared is sent round to other Fellows of the Society, who are acquainted with the work of the candidate, and who sign it as a testimony that they think he is worthy of election. In this way when the proper time arrives some fifty or sixty papers are sent in to the Council for their consideration. In the Council itself we may assume that the selection of the fifteen is made as carefully as possible in view not merely of individual claims but of the due representation of the different branches of science. It is not for us to state the safeguards or mode of procedure adopted, but we think we may say that the slightest action or appeal to any member by the candidate himself would be absolutely fatal to his election. Finally, we may say that, years back, when a heavy entrance fee had to be paid, there were cases in which the question had to be put to one whose friends were anxious to see him elected, whether he would accept election. The small yearly subscription of 3*l.*, now the only sum payable, makes even this question unnecessary at the present time.

ON MEASURING THE VIBRATORY PERIODS OF TUNING-FORKS

THE tuning-fork when its number of double vibrations, to and fro, in a second, or briefly its *frequency*, has been ascertained, is a most convenient instrument for measuring minute divisions of time. As such it is now extensively used for physical, physiological, and military purposes (velocity of bullets and cannon balls). The antecedent difficulty of ascertaining the frequency, is however very great. The old processes, sufficient for roughly ascertaining musical pitch, and depending upon wires of known weight, length, and tension, or the action of the siren, are totally insufficient for modern purposes. It was the contradictory nature of the results furnished by the monochord in the division of the Octave into twelve equal parts that led Scheibler to his system of a series of tuning-forks differing from one another by known numbers of vibrations, leading to countable beats, and extending over an Octave. Nothing can be more convenient to use than such a series of forks for all musical purposes. They enable the frequency not only of any small as well as large tuning-fork, but also of any sustained tone to be ascertained within one-tenth of a vibration, that is, one vibration in ten seconds. The writer has for some years been in the constant habit of using such a set of forks with the most satisfactory results. His own forks were measured by Scheibler's (exhibited in the Historic Loan Collection of Musical Instruments at the Albert Hall this year), but extend over a greater range, from about 224 to about 588 vib., that is, rather more than an Octave and a major Third. The great advantage of such a tonometer is extreme portability, immediate application to any sustained tone (even that of a pianoforte string), and the independence of the result from any (almost always imperfect) estimation of unison by a musical ear. There are of course antecedent difficulties in ascertaining the pitch of each particular fork, but these are overcome by patient observation, the extension of the series beyond an Octave furnishing in itself the required check.

Scheibler died in 1837. In 1879 Prof. Herbert MacLeod and Lieut. R. G. Clarke, R.E. (*Proc. R. Soc.*, vol. xxviii. p. 291, and *Philosoph. Trans.*, vol. clxxi. p. 1) invented an optical arrangement, which under proper management (but the manipulation was very difficult) gave excellent results for large tuning-forks, like those of Koenig. And in 1880 Koenig (*Wiedemann's Annalen*, 1880, pp. 394-417) invented a clock method for ascertaining with extreme accuracy the frequency of one large standard fork of 64 vib. at 20° C. Before both Prof. MacLeod and Dr. Koenig, Prof. Alfred Mayer, of Hoboken, New Jersey, U.S., had invented a most careful and ingenious electrographic method, of which a full account has just appeared in vol. iii. of the *Transactions* of the National Academy of Sciences, U.S.[1] Briefly this last method consists, first, of making the tuning-fork itself, by means of an added style of extreme tenuity, scribe its vibrations as sinuosities in a curve on a revolving cylinder of smoked paper, an old conception; and, secondly, of determining the exact number of such sinuosities as occurred in a second, by means of electricity, which was entirely new, and in which lies the pith and difficulty of the method.

When in 1879 the writer was collecting materials for his "History of Musical Pitch" (*Journ. of Soc. Arts*, March 5 and April 2, 1880, and January 7, 1881), it became necessary to verify Scheibler's forks, and to do so he had five large forks constructed, giving the pitches of certain forks preserved in the Conservatoire at Paris. These forks he measured with great care by Scheibler's tonometer, and then Prof. MacLeod measured them by his process, after which they were sent to America to be measured by Prof. Mayer (the particulars of his measurements of these forks are given in his paper cited above), and on their return they were remeasured by the writer with the scribing-points on, and by Prof. MacLeod with the scribing-points on and off, in order to ascertain the flattening caused by the scribing-points, and also any losses that might have been occasioned by the journey. The sum of the two affected only the second place of decimals, except in one fork, where they amounted to 0·2 vibrations. By adding these, and also correcting for temperature, the result was an agreement of all the three methods within 0·1 vibrations.[2]

But Prof. Mayer's results are given to three places of decimals, which it would be extremely difficult to check, not only because of the delicacy of the measurement, but on account of the alteration of pitch by temperature, and the uncertainty which prevails over the coefficient of alteration. Thus for 1° F. Prof. Mayer considers this coefficient to be ·00004638, or 1 in 21561; Prof. MacLeod takes 1 in 20,490, and Dr. Koenig as 1 in 16,097, or in 16,112, or 16,000. The writer's own experiments, between 59° and 175° F., gave 1 in 18,280. For all ordinary purposes 1 in 20,000 may be conveniently used. But the coefficient certainly alters with the size, shape, and quality of the fork observed, and hence it is necessary to correct each observation for temperature separately, before taking the mean, as Prof. Mayer has done. Under these circumstances, at most 2 places of decimals (perhaps only 1) out of 3 of Prof. Mayer's means can be trusted. That is, it is doubtful whether his process for measuring the frequency of tuning-forks is superior to Scheibler's, properly carried out.

The difficulties of the process, which caused Prof. Mayer much trouble to overcome, may now be referred to. The kernel of the method consists in a very exact assignment of the beginning and end of each second on the sinuous curve of vibrations. This is obtained from a clock, the rate of which has to be ascertained. Its pendulum is armed with a point which cuts through a globule of mercury in a cup, screwed up to be small and rigid, and, as this globule rapidly becomes oxidised, by the passage of electricity, it must be renewed for each experiment. The spark from the inductorium at every contact of the pendulum and mercury, must make a *single* perforation of the smoked paper covering the cylinder. To effect this the strength of the current must be carefully regulated, as otherwise a great number of holes may be made. The paper is very interesting on this point, which is well illustrated by experiments and a diagram. Other precautions are necessary, but the above two are the most important. The primary coil of the inductorium and the clock (through the pendulum and globule of mercury) are placed in the circuit of a voltaic cell. The fork and cylinder (separated from the style by the thickness of the smoked paper) are placed in the secondary circuit of the inductorium. The work of the fork on the paper in scribing was found not to flatten by more than ·004 vib. The flattening from the appended scribing-point was shown by Prof. MacLeod's measurements of the writer's forks to vary from ·021 to ·0475 vib. It therefore always sensibly affected the second place of decimals, showing that the results for determining the frequency of an unarmed fork, when the effect of the arming could not be determined (as it cannot be by Prof. Mayer's method), could not be trusted beyond one decimal place. This limit can be reached very simply without all this apparatus and these precautions, by simply counting the beats of good forks within beating distance of each other. Prof. Mayer's method, therefore, does not surpass Scheibler's for simply determining the frequency of tuning-forks, but is fully equal to it, provided the forks are sufficiently large. Neither Prof. Mayer's nor Prof. MacLeod's process is applicable to small forks. The writer is doubtful whether the passing of a current through one prong of the fork and not the other may not affect the period of the fork. The necessity of screwing the fork on to a block (as indeed of screwing it into a resonance box) is always dangerous from the possibility of twisting the prongs. The writer has known of a fork which was thus considerably altered. The frequency of a fork screwed on to block in this way is not the same as that of a fork on a resonance box. Prof. Mayer has himself, in his paper, determined that the amount of correction for support and scrape may amount to – ·026 vib. Prof. Mayer does not renew the excitation with a bow during the same observation, as Prof. MacLeod had to do, and he has shown that the frequency is practically independent of the amplitude of vibration.

Prof. Mayer did not himself apply his instrument to determine the frequency of forks generally, but, as he states in the title of his paper, specially as a chronoscope. In that case the above difficulties disappear. What is wanted to know is the exact number of vibrations of the scribing-fork as it scribes, affected by all the circumstances mentioned—screwing, scribing, passage of electricity, &c. We are not in the least concerned to discover the frequency of the unscrewed, unarmed, unelectrified fork. Even temperature is of no consequence, provided it be uniform during the experiment. The velocity of rotation of the cylinder is also immaterial, provided it be constant for one double vibration, which can hardly help being the case for such a small fraction of a second. There is only one source of error, the inequality of the seconds' pendulum, arising from the globule of mercury being of a sensible magnitude, so that an appreciable time is occupied in traversing it (eliminated by counting the sinuosities for every two seconds instead of every second), and the inevitable want of true centering of the globule and pendulum (eliminated by taking a mean). Prof. Mayer's arrangement then becomes an extremely simple and also an extremely accurate means of measuring short intervals of time within, to a certainty, one-hundredth of a vibration of the fork. Thus, if the fork gives 400 vibrations in a second, the measurement would be correct to one-forty-thousandth part of a second!

Prof. Mayer concludes his very valuable and interesting paper—which is recommended to the attention of all experimenters requiring accurate chronoscopic observations—with showing the arrangement for experimenting with this chronoscope "on the velocities of fowling-piece shot of various sizes projected with various charges of powder from 12- and 10-gauge guns," with a diagram giving the

[1] "On a method of precisely Measuring the Vibratory Periods of Tuning-Forks, and the determination of the Laws of the Vibrations of Forks; with special reference of these Facts and Laws to the Action of a Simple Chronoscope."

[2] Prof. Mayer measured, at temperatures varying from 63·3 F. to 69·25 F. The standard temperature of the writer was 59° F. = 15° C., the temperature at which the Diapason Normal in Paris has been settled. It may be mentioned that in Prof. Mayer's tables xiii. and xiv. of this paper, the titles have been transposed; the first related to the Tuileries fork, 434 vib., and the second to the Feydeau fork, 422·8 vib., and not conversely as printed.

position of the wires and make-circuit lever, and tables of the results, and says, finally:—

"The simplicity and inexpensiveness of the chronoscope we have described in this paper, its accuracy, and the ease with which it is used, must commend it to all who will give it a trial under the conditions of the action which we have endeavoured to set forth in this paper. Another of its advantages is that its records on the paper covering the cylinder are easily rendered permanent by drawing the unsmoked side of the paper over the surface of a dilute solution of photographic negative varnish contained in a wide shallow dish. On the records may be written with a blunt style the nature of the experiments they record before the carbon is fixed by the varnish, and then they can be bound together in book-form for preservation and reference."

ALEXANDER J. ELLIS

HINTS ON THE CONSTRUCTION AND EQUIPMENT OF OBSERVATORIES FOR AMATEURS

IF it were necessary to offer any apology for the short series of articles of which the first is now presented to the readers of NATURE, it might be found in the fact that, so far as I know, nothing fulfilling the above title has been put into circulation in England for more than forty years. This is the more remarkable when one considers the great development of astronomy in this country during the present generation, a development the credit of which is far more due to amateur effort than to the influence of Governments or public establishments. The reason I have fixed upon the year 1844 is that that was the year in which Admiral Smyth published his well-known "Bedford Catalogue of Celestial Objects," to which he prefixed certain chapters dealing with the construction and management of small observatories.

Those chapters have never been reproduced in any form, partly, no doubt, for the reason that they are a good deal out of date; but they are still capable of furnishing many useful hints to any one who wishes to write on the subject of observatories.

It is not too much to say that the Bedford Observatory has directly or indirectly served as the model for nearly all the private observatories of moderate dimensions since erected in England, and it is equally certain that, whatever may be the changes which considerations of finance, or architecture, or geology, may render expedient in particular instances, no important alterations need be made in the main features of the Bedford Observatory, although upwards of half a century has elapsed since it was erected, and more than forty years have passed away since it was pulled down.

In order to compress as much information as possible into a small compass I propose to classify what I have to say in such a way as shall successively conduct the reader step by step through the stages which he himself will have to pass through between the time when he determines to erect an observatory and the time when he finds himself the happy possessor of the completed building. Of telescopes as such I shall here say nothing, and the only other prefatory remark which seems requisite is this: that an amateur astronomer with only a given and moderate sum of money to lay out will do well to appropriate an adequate part of his funds to the purchase of a fairly good stand and of a suitable structure in which to house his instruments, rather than spend too much on his tube and then be obliged to starve the stand and to put up with inadequate shelter from the weather or no shelter at all. To begin, therefore, at the beginning.

The Choice of a Site.—As to this the amateur will probably in most cases be obliged to suit himself as best he can. If his garden offers any varieties of site, he should endeavour to secure one on slightly rising ground, with an uninterrupted horizon to the south (for meridian purposes) and to the west (for comets and inferior planets in the vicinity of the sun at sunset). A clear horizon to the east is of less moment, unless searches for comets before sunrise are intended to be systematically carried out.

In making preparations for building an astronomical observatory—and occasionally, indeed, for other purposes—it is necessary to know how to set out a meridian line. Of course this may be done by means of a mariner's compass (correcting for the magnetic deviation); but there are other ways of doing this independently of a compass, and as it is not always easy to ascertain the deviation a statement of at any rate one of these other ways, as given by Challis, will be useful. Set up a pole at the spot through which the proposed meridian line is required to pass, using a plumb-line to ensure the pole being vertical. Draw around the pole as a centre several concentric horizontal circles, and mark the points of coincidence of the extremity of the shadow of the pole with these circles both before and after noon. Then if the two points on each circle be joined by a chord the mean of the directions of the middle points of the chords from the pole will be approximately the direction of the meridian line. This method answers best about midsummer when the sun's diurnal path is high in the heavens, and the change of declination is small. A little forethought must be displayed in suiting the dimensions of the circles to the height of the vertical pole employed.

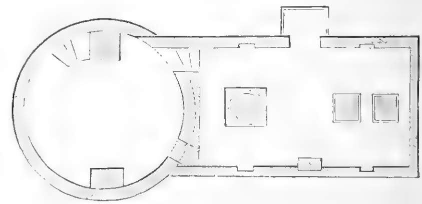

FIG. 1.—Ground plan of the Bedford Observatory.

Foundations.—The foundations of an observatory are a matter of great importance, and unless a rock[1] or chalk bottom can be readily obtained, an artificial bottom of concrete, more or less thick according to the height of the intended superstructure, must be made. This of course applies to the piers which are to carry instruments. In the case of the observatory itself, especially if the material of the fabric is to be of wood, which is so often used, the ordinary precautions against settlement taken by a competent builder will suffice. As no fire-place is permissible in an observatory because of the disturbing currents of air to which fires give rise, special precautions must be taken to protect the building and its contents against damp, and the consequences thereof. In heavy clay soils clear away the soil all around the outside of the observatory by making a trench, say 10 feet wide and 4 feet deep, and fill up the excavation with broken bricks, coarse gravel, or other hard porous material. Provide by suitable gutters and pipes, that all rain-water falling on the observatory shall be carried away to a distance as quickly as possible.

Details of the Structure of the Observatory.—Fig. 1 represents the ground plan and Fig. 2 the elevation of the Bedford Observatory. The external dimensions were about 35 feet by 13 feet 6 inches. The building was divided into two apartments: (1) an equatorial room, circular, and 15 feet in diameter on the inside; and (2) a transit-room, 17 feet by 12 feet on the inside, and 10 feet

[1] A rock foundation is not necessarily the most stable possible, and some authorities deem a sandy substratum best.

high. At Bedford the transit room contained a transit circle and a transit instrument, with a clock so placed that it could be used with either, as wanted; but an ordinary amateur will only need to have one meridian instrument, and the surplus space may advantageously be partitioned off to form a calculating-room, or the

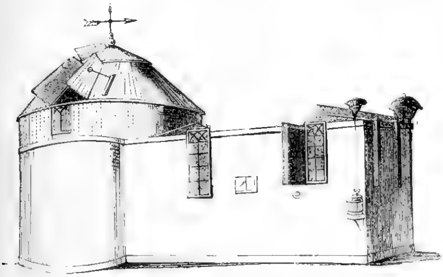

FIG. 2.—Elevation of the Bedford Observatory.

space may be used as an ante-room, and the entrance door put there, and not on the north side, as at Bedford.

It will now be convenient to describe the several parts of an observatory more in detail.

The Equatorial Room.—The equatorial being the principal instrument in every amateur's observatory, the provision made for its accommodation deserves attention first. It is not an uncommon practice to arrange that the floor of the equatorial room shall be 2 feet or 3 feet below the level of the adjoining room, and where a large equatorial is worked with a small transit instrument used merely for setting the clock, and economy and difficulties of site have to be considered, a sunken equatorial room may be unavoidable. But all the same the practice is highly inconvenient and ojectionable. An observer should be able to move rapidly from one part of his observatory to another in the dark, and without having to think of steps up or steps down. Moreover, in order to secure free internal ventilation nothing more substantial than a green baize curtain should separate the equatorial room from the transit room, and it is obviously not safe to use such

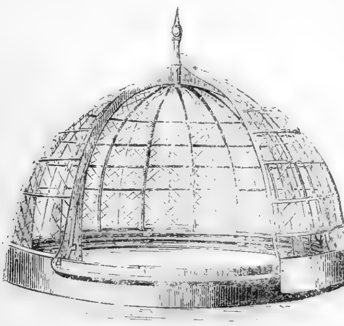

FIG. 3.—Diagram showing ribs of a dome intended to be covered with copper or sheet iron.

a curtain where it will conceal a difference of level of 2 feet or more.

Fig. 1 contemplates an equatorial of what is called the "English" form, with two separate piers for the support of the polar axis; but this construction of equatorial has become almost obsolete, owing to its numerous practical disadvantages, and the "German" form, with one pier and pillar, centrally placed, is now all but universally used, at least by amateurs.

The construction of a roof for an equatorial room (technically called the "dome," whatever may be its precise form) is a great *crux* to the intending builder of an observatory. Theoretically the hemisphere is the proper form, and roofs truly hemispherical are occasionally met with; but they are extremely troublesome and expensive to make, and can only be tackled by professional engineers.

Fig. 3 represents the skeleton framework of such a dome of large dimensions, before the sheet copper, or other material to be employed in covering it, has been been put on. Of late years, especially for large observatories, "drum" domes have come much into use as comparatively easy to construct, and capable of being made strong and watertight; but they offer much resistance to the wind, and architecturally are bound to be ugly.

For the purpose of protecting the smaller sizes of equatorials, say those from 4 inches to 7 inches in aperture, a polygonal dome is recommended. Or, in the case of equatorials of the smallest size, say from $2\frac{1}{2}$ to 5 inches, the roof of the equatorial room may be flat, and arranged to open by sliding it to one side. Such a sliding roof should not be quite mathematically flat but should have a slight inclination, to throw off the rain.

Whatever be the form of the dome chosen the problems,

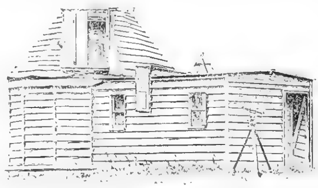

FIG. 4.—Wooden Observatory erected at Eastbourne in 1854.

how to uncover a slit in it, and how to move the whole of it, are matters which require in all cases careful consideration. Where the dome is a large one, say more than 12 feet in diameter, the shutters which close the slit should slide. They may slide laterally on a suitable staging (as in Fig. 4), or they may slide up and down. The latter is a very convenient expedient, especially when the observatory is to be erected in a situation exposed to strong winds, or when the telescope is to be much used on the sun; for the observer can open just so much space as will uncover the whole aperture of the telescope, and can keep himself and the greater part of his telescope protected from the direct impact of the wind, or the direct rays of the sun, as the case may be. When arranged in the best form the shutters will be three or four in number, each protecting a third or a fourth of the slit, measured vertically. Each shutter must have its own rabbet, and its own ropes and pulleys, in order to enable the observer to open at one time only so much of the whole slit as is necessary to enable him to scrutinise the particular portion of the heavens which he desires to examine. The advantage of thus being able to shelter himself and his telescope will soon be appreciated in windy weather, or under a meridian sun by the owner of an observatory fitted with sliding shutters.

Another important matter is the question of the bearings on which a dome is to be mounted. Large domes can only be made to move with facility by the aid of mechanical appliances which are often in practice both complex and cumbersome, and needing much muscular effort on the part of the person who has to move the dome. Where the weight of this does not exceed a ton, a set of grooved wheels running in a concave wall-plate of iron generally works well. For weights beyond this, special mechanical appliances must be used, which it is foreign to my present purpose to treat of. On the other hand, light domes—by which is meant domes up to, say, half a ton—are best dealt with by being mounted on iron balls (cannon balls in fact) travelling on a circular wall-plate, and kept in place by an upper plate, the arrangement being such as is indicated in Fig. 5.

The ironwork may be simplified in character and lessened in weight if the upper plate, which in Fig. 5 is, like the lower one, a solid casting, is replaced by two detached rails about an inch square in section and placed about 3 inches apart. The balls need only be three in number where the diameter of the dome does not exceed 10 feet. If the diameter is greater than that a fourth ball may be desirable in order to distribute better the weight, and lessen the risk of the framework of the dome being strained. The diameter of the balls may be 4 or 5 inches (say 24-pounder or 32-pounder balls), and the more truly spherical they are the less the friction, and consequently the less the muscular effort, required to impart motion to the dome; and to this it may be added the less likely are the balls to approach one another after being some time in use and so in a sense dismount the dome. When this does happen the dome must be slightly prised up by means

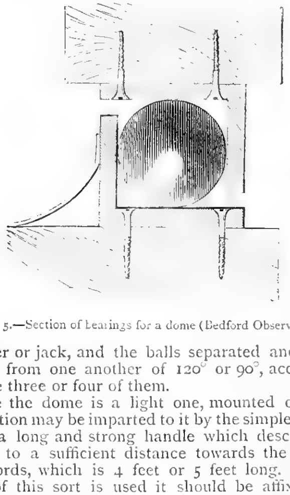

Fig. 5.—Section of bearings for a dome (Bedford Observatory)

of a lever or jack, and the balls separated and set at a distance from one another of 120° or 90°, according as there are three or four of them.

Where the dome is a light one, mounted on cannon balls, motion may be imparted to it by the simple process of pushing a long and strong handle which descends from the roof to a sufficient distance towards the floor; in other words, which is 4 feet or 5 feet long. Where a handle of this sort is used it should be affixed to the dome by strong screws or bolts, exactly opposite the shutters which cover the main opening, because when so placed the observer can grasp the handle and bring the openings exactly to that part of the heavens to which he has pointed his telescope, and can be sure that he has done so. In this facility of being able to watch how far the dome is moved resides the great advantage of the fixed handle; its disadvantage is that the observer in moving the dome has to follow it himself by walking around on the floor. To obviate this inconvenience, such as it is, some prefer a fixed wheel permanently attached to some one place in the wall of the observatory, and having cams in its periphery to catch suitable pins attached at short intervals to the inside circumference of the revolving dome.

Whatever may be the form of the dome, it is evident that in plan it must at the bottom be circular, and that the wall-plate must be circular also, and of the same dimensions. But the plan of the equatorial room, as regards its walls and floor, is another question. Where the room is large, say 15 feet or 20 feet, or more, in diameter, it will be best that it also should be circular, or perhaps octagonal. Where, however, the dome is not more than 12 feet across, and consequently the whole establishment is on a small scale, there are great advantages in making the equatorial room square. In such a case the corners will be found very useful for various purposes: for instance, in one a desk or writing-slab may be fixed; in another, the clock; in a third, a lamp; whilst the fourth corner may take a chair or a stool. In other words, the corners become available as places of refuge for things and persons whilst the observer is turning the dome round from one part of the heavens to another. Moreover, the cost of building a square room is less than the cost of building a polygonal one, because the difficulty is less, be the material brick or wood. If wood is employed for the walls of an observatory, it will in all cases be desirable to place the frame on a dwarf wall of brickwork rising at least 2 feet above the general level of the ground.

The floor must be supported on joists, trimmed so as to form square frames around the piers which are to carry instruments. This will enable the floor-boards to be fixed firmly, yet quite clear of the piers, and will prevent tremors, caused by persons passing over the floor, being conveyed to the piers, and so to the instruments. A free circulation of air must be secured by means of small brass ventilating gratings suitably disposed around the floor near the walls.

Making due allowance for the different purposes for which it is to be used, many of the remarks just made with respect to the equatorial room will apply also to the transit room. The main part of the roof is a fixture, but an opening about 1 foot 6 inches wide has to be made right across the top, and to be continued into the north and south walls from the eaves downwards towards the floor, so as to enable the observer to sweep the meridian with the transit instrument from the south horizon through the zenith to the north horizon. The openings must be protected by shutters, which may either slide or lift. For large observatories Grubb has devised a form of balance shutter which swings, and is said to work well.

In cases where the top transit shutter, which constitutes part of the roof, is in the form of a flap and lifts, it must be counterpoised by a weight or weights travelling up and down inside the room. The vertical shutters must be treated as casements, and be fitted with handles and fastenings accordingly. The remarks made in speaking of the equatorial room as to the advantages offered by sliding shutters or sashes, apply equally to the case of sliding shutters for a transit room.

Light should be obtained for an observatory by independent windows, and not, as in Fig. 2, by panes of glass inserted in the shutters; for glasses are very apt to get broken by the constant moving of the shutters.

The transit instrument as such I need not describe in detail, but it may be worth while to show how a transit instrument is mounted where space is no object, and the instrument is intended for the determination of Right Ascensions rather than for the commonplace purpose of setting a clock.

The transit instrument at Bedford consisted of a telescope of 3½ feet focal length furnished with an object-glass whose aperture was 3¼ inches; the telescope was supported by broad cones forming an axis 28 inches long, the pivots of which rested on covered Y's offering a surface of polished Brazilian pebble an inch in bearing, and which (owing to their bases being hemispherical and working in corresponding sockets) held their proportionate weight, as well as ensured the axis of the pivots being always strictly in the same right line. The Y's were placed on improved chucks whose azimuthal and vertical motions were effectually secured from dust and injury, and left the shoulders of the pivots just sufficient room for moving without friction; the Y's were morticed upon 2 piers of Portland stone rising 5 feet 7 inches above the floor, and which with their bases weighed a ton each. The axis of the instrument was perforated at one end in the usual way for the admission of light from a lamp at night, but it also contained a contrivance for regulating, by means of a milled head on the telescope tube, the light falling on the wires; and there was, moreover, a rack-screen to the lamp for the same purpose. In the optical focus were five principal vertical wires (besides two for the Pole-star) crossed by one horizontal wire; with a slide and divided scale for bringing the axis of the eye tubes exactly over the respective wires, and thereby destroying parallax. This part of the tube was also fitted with a simple means for adjusting the eyepiece to the solar focus, and for taking out the frame bearing the spider lines in case they needed examination or repair. For setting the telescope the eye-end was furnished with two circles, 6 inches in diameter, each provided with a level and showing altitudes and zenith distances. But it is strongly recommended that such circles should in all cases be graduated and adjusted so as to show declinations.[1]

Setting circles attached to the eye-ends of telescopes are so extremely convenient for approximate settings that it is a matter of surprise that they are not more generally used. They are thought to have been invented by Troughton, and to have been first applied in 1816 to the Greenwich transit instrument. As to this, Smyth has a note as follows:—"Mr. Jones lent me a note-book of the late Mr. Walker, of *Eidouranion* memory, in which he describes a visit he made to the celebrated Jesse Ramsden in 1780; and mentions that he was shown an ingenious mode of elevating a transit instrument by a circle of about 3 inches diameter and a level at the eye-end. The vernier fixed and the circle with its attached level movable. To this statement is the sketch of a telescope so fitted, the accompanying portion of which I traced."

FIG. 6.—The transit instrument of the Bedford Observatory, with observing chair and clock.

Meridian Mark.—This is an accessory to the transit instrument, so useful and so convenient that it is a matter of surprise that a meridian mark is not more generally provided in connection with transit instruments. It affords by day, and, if illuminated, also by night, a means of verifying the meridian adjustment of the transit instrument. Fig. 8 represents the meridian mark used in connection with the Bedford Observatory. A plate of brass about 4-10ths of an inch thick, 5 inches long, and 3 inches wide was fastened by four screws, passing through its corners, to a stone, into which four brass sockets to receive them had been made fast by molten lead. On this plate it was arranged that another of the same thickness should slide; this was $3\frac{1}{2}$ inches long by $1\frac{1}{2}$ inches broad, and was attached to the former by dove-tailed side-pieces, and was capable of being adjusted by two long screws pressing against its ends. In the sliding plate there were four slots to receive four capstan-headed screws, by means of which the sliding-plate could be firmly made fast to the fixed plate after the mark had been duly adjusted to the meridian. This done, the end screws were withdrawn to prevent the possibility of their

[1] If information is needed as to how this is to be brought about reference may be made to Challis's "Lectures on Practical Astronomy," p. 26.

being tampered with and the mark displaced from the meridian. On the sliding plate there was soldered a square piece of silver exhibiting a well-defined black cross, the centre of which was to mark the actual meridian. As this cross taken by itself hardly afforded sufficient vertical length for comparing the wires of the transit a small circle of silver (with a black dot in its centre) was placed above the cross as an auxiliary mark. This silver circle, like the larger silver plate below, was capable of lateral motion by means of capstan-headed screws which

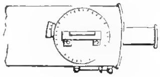

FIG. 7.—Setting circle devised by Ramsden.

could be removed when the dot had been brought exactly over the cross below. The stone to which the mark was fixed was firmly morticed into a dwarf pier, to guard against lateral movement, and the whole superstructure was firmly bedded on a solid substructure sunk into the earth. It is of the utmost importance to guard against settlements likely to cause any lateral movement, for it must be remembered that with a 50-foot radius a displacement of about 3-1000ths of an inch is equivalent to one second. The remaining and important part of the arrangement at Bedford was a 4-inch lens of 49½ feet focus, being exactly its distance from the diaphragm. This lens was mounted in a brass collar, and having been attached by screws to a plate of cast-iron, was let into the wall of the transit window in a line with the transit instrument and the meridian mark. It is evident that the rays of light from the meridian mark become parallel after passing through the lens, and that the diaphragm can therefore be viewed through the telescope of the transit instrument as adjusted to solar focus. Another consequence of the rays being rendered thus parallel, is that no parallel motion of the transit axis would cause a change in the place of the object seen, so that the meridian is a line drawn from the *diaphragm* through the axis of the lens; and provided that these two points remain rigidly permanent, they offer all the advantages of a very distant meridian mark. And after all, a distant mark when obtainable can still be used as a check to the home mark. It will often happen that an observer will be able to find at the distance of a mile or two, or even of several miles, some well-defined line or point—*e.g.* a window sash, or the pinnacle of a church, or a piece of squared stone, which will serve him as a meridian mark for the simple reason that it lies in the meridian of his transit instrument.

Clocks.—A clock is a very important article of furniture in every observatory.

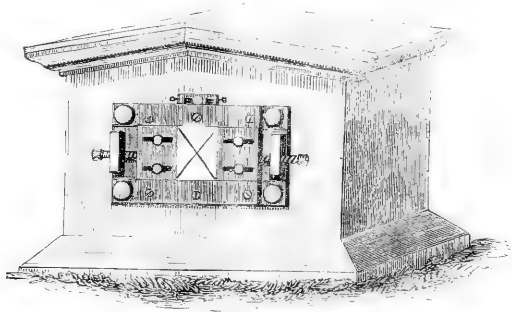

FIG. 8.—Meridian mark.

Whilst a proper sidereal clock showing twenty-four hours is what an amateur should have, he can very easily make shift with a much less pretentious time-piece, especially if his equatorial is provided with the best modern form of driving clock which only requires to be set once, or occasionally, during an evening's work. Indeed all that is essential in such a case is really a good dining-room clock (with its pendulum adjusted to sidereal time) which once set at the commencement of an evening by means of a transit instrument can be depended upon to maintain a tolerably even rate for half a dozen hours. The price of sidereal clocks for observatory purposes has been much reduced of late years, and from 20*l.* to 30*l.* will now command a fairly good one.

Where an observatory includes a transit room the clock should of course be placed so as to be visible both to an observer sitting at the transit instrument and facing the direction in which transits are most usually taken (that is, for the northern hemisphere, south) and also visible to an observer working with the equatorial. This desirable combination makes it expedient that the equatorial room should be at the west end of the buildings; but local reasons connected with the site of the observatory may not always render this possible.

For the clock there should be provided a stone pier constructed and isolated with much the same precautions as those already suggested in respect of the piers prepared to carry the telescope.

On the top of the clock case there is sometimes placed a "Hardy's noddy." This is a small and sensitive inverted pendulum inclosed under a glass bell and standing on a frame provided with three adjusting screws to level it. The use of the noddy is to discover whether the pendulum of the clock imparts any motion to its supports. But this is a refinement with which in a general way amateur observers need not concern themselves.

Meteorological Instruments.—Although an astronomical observatory is one thing and a meteorological observatory is altogether another thing, yet every astronomical establishment should be provided with a few of the more ordinary meteorological instruments, even though their owner does not profess to be a meteorologist. All astronomical observations are in a measure affected by changes in the temperature and humidity of the air; consequently, a self-registering maximum and minimum thermometer, a hygrometer, and a rain-gauge should be regarded as indispensable accessories to every observatory. No doubt, also, the desirability of having a barometer will naturally suggest itself, though its astronomical usefulness is very small indeed—by which I mean that changes of pressure only require to be taken account of in the very exact instrumental observations carried out in first-class observatories. It is also important that a respectable weathercock should be in sight, for the direction of the wind exercises, as is well known, a potent influence on the condition of the air, as revealed by the scrutiny of a celestial object through a telescope.

A good "Six's" thermometer is quite good enough for general purposes, although not a self-registering instrument of the highest scientific precision. As a hygrometer, "Mason's wet-and-dry-bulb" instrument leaves nothing to be desired.

The one special precaution of a meteorological character to be taken in connection with all astronomical observations, whether made in an observatory or in the open air, is that equality of temperature should be secured everywhere. Whilst the due ventilation of the observatory should at all times be provided for, it is absolutely essential, in order to insure good results with every kind of instrument, that all doors and windows should be thrown open, so as to obtain a free current of air everywhere for fully half an hour before observations are to be begun; in hot summer weather, indeed, a longer time will generally be found necessary. The object of these precautions is obvious enough: it is to insure the inside air and the metal of the instruments being cooled down (or, as it may sometimes happen, being warmed up) to the temperature of the external air. In order to learn whether this equality exists, every observatory should have a thermometer outside as well as inside. The former should be hung on the north side, away from the sun, and, if possible, not actually in contact with the observatory itself. G. F. CHAMBERS

(*To be continued.*)

NOTES

WE learn with much pleasure from *Science* the election of Prof. E. S. Holden to be President of the University of California, and Director of the Lick Observatory. Prof. Holden's resignation as Director of the Washburn Observatory at Madison, Wis., takes effect on January 1 next. His appointment as Director of the Lick Observatory will hardly be a matter of surprise to those who are aware that, as consulting astronomer, he has virtually had the direction of the work as it has progressed, visiting the site on Mount Hamilton in 1881, and again in 1883 and 1884. Very happily the choice both of the Lick trustees and of the regents of the University has fallen upon Prof. Holden. It is understood that, in his letter of resignation to the regents of the University of Wisconsin, he strongly urges the name of Prof. W. A. Rogers, of Harvard College Observatory, as his successor.

THE wealthy American, Senator Stanford, proposes to establish a Californian University. He intends to give to it, besides estates worth 5,300,000 dollars, a donation in money increasing its endowments to 20,000,000 dollars. The University will be located at Palo-Alto, thirty miles from San Francisco, and is apparently to be modelled somewhat after the plan of the Johns Hopkins institution.

THE prospectus has been issued by Herr Fischer, publisher, of Jena, of a new scientific periodal entitled *Zoologische Jarhbücher: Zeitschrift für Systematik Geographie und Biologie der Thiere*, which is to be brought out under the editorship of Dr. J. W. Sprengel, of Bremen. Notwithstanding the vast number of scientific journals, both author and publisher think that this department of science does not receive the attention which it deserves. It is not excluded, they say, from scientific periodicals; but communications relating to it appear more or less as strangers by the side of others. The new periodical will be wholly devoted to this class of subjects. In the first section the papers will, for the most part, be of a higher kind than the mere description of new species, except those for which no special journal exists. The geographical section will contain studies on the distribution of all kinds of animal and vegetable life, and special attention is promised to the biological section. Contributions will be received in German, French, English, and Latin. The periodical will appear quarterly, each four issues making a volume.

THE success of the last electrical exhibition at the Paris Observatory was so complete that the International Society of Electricians is preparing another for next spring.

A GENERAL meeting of members of the French Association for the Advancement of Science has been summoned to approve of the fusion with the Société Française. Lectures and meetings will take place this year under the patronage of the united societies as a single body.

THE well-known electrician, Dr. James Moser, who was working for some time at Prof. Guthrie's laboratory, has been appointed as *privatdocent* at Vienna University.

THE Colonial fisheries are to form a prominent feature at the Indian and Colonial Exhibition which is to be held next year. The Aquarium will be considerably enlarged, and special tanks are now being prepared for the reception of the various fish from the Colonies. A tank of colossal proportions is to be allotted for the purpose of exhibiting turtles in large numbers which will be despatched from India together with other specimens in the early part of next year. We do not yet know what fish are to be forwarded from the various colonies, but the utmost care will have to be exercised and the most perfect arrangements made in order to provide for their various necessities. The collection promises to be one of great interest and value, although its success all depends upon how the fish withstand the long journeys to which they will be subjected.

TOWARDS the end of October the remarkable sun-glows were again seen at Stockholm. In the western horizon a yellow cloud-bank, strongly illuminated, appeared behind a number of tiny clouds, greyish in colour, the sky above the former, to a height of about 45°, being lurid, entirely colouring the clouds. Later on in the evening the glow imparted to the edges of the clouds the most remarkable reflections of colour, varying from ochre to yellow, violet, and pink, with shadings of blue. At times the higher-lying clouds formed most remarkable formations. It seemed that the glow was situated between cumulus and cirrus clouds.

ON October 21, at about 5 a.m., a brilliant meteor was observed at Skaadö, on the south-east coast of Norway. It appeared first near the zenith, and describing a circle of about 70°, disappeared in the south-west, about 20° above the horizon. In spite of the sky being covered with clouds, and its being still dark, the country around was lit up as in daylight, objects being clearly discernible at a great distance. As no sound or explosion was heard, it is assumed that the track of the meteor lay in the upper parts of the atmosphere.

SOME Thames trout are being spawned at Sunbury by the Thames Angling Preservation Society, who are doing their utmost to replenish the stock of this fine species of Salmonidæ, which, unhappily, have now become a rarity. The ova will be incubated by the National Fish Culture Association, and the fry will ultimately be deposited in one of the Thames nurseries.

THE Catalogue of the Library of the Royal Society of Tasmania is a considerable volume; and it is a matter of some surprise to find that men of science in this distant colony have such an excellent library as this. It embraces every class of literature, and appears especially rich in periodicals, and in works relating to Australasia.

THE last "Circular" of the Johns Hopkins University Library contains a list of the periodicals, including the scientific and literary publications of various societies, regularly received. Although newspapers and official reports are omitted, the list extends over eleven closely-printed columns, and probably contains the name of every periodical in the world in any way connected with science.

AN interesting bi-monthly periodical has just made its appearance in Colombo. It is entitled the *Taprobanian; a Dravidian Journal of Oriental Studies in and around Ceylon in Natural History, Archæology, Philology, History, &c.*," and is edited by Mr. Nevill, F.Z.S., of the Ceylon Civil Service. The first number contains various notes and queries, relating mainly to scientific subjects, and articles on Tamil inscriptions in Ceylon, comments on Ptolemy's geography, on Ceylonese inscriptions in the Asokha dialect, archæological reports on Ceylon (No. 1), and on the Vaedda dialect. The whole of the contents of the thirty-two pages of the first issue is from the pen of the editor, who hopes to make his periodical a storehouse of details, available hereafter for the elaboration of any special subject connected with the Tamil and other Dravidian races. He promises to do his utmost to procure for investigators in Europe, America, or elsewhere, any local information of scientific interest that they may seek. We hope the venture will have the success which the editor's learning and enterprise so well deserve.

WE are glad to notice the re-appearance of the *Orientalist*, another Ceylon periodical, containing articles of much scientific interest, and which has been noticed in NATURE. It ceased publication for some months, but the editor is now publishing double numbers to make up for lost time, which, it is only fair to add, was due to negligence of subscribers, not to that of its learned editor.

THE present number (x. No. 23) of *Excursions et Reconnaissances* of French Cochin China contains the fourth part of M. Landes's article on Annamite tales and legends; but it is mainly occupied with the continuation of M. Tirant's long account of the fishes of Lower Cochin China and Cambodia.

THE inhabitants of Srinagar, Cashmere, have again been thrown into a state of alarm and consternation at the recurrence of earthquake shocks there. The first shock—a severe one—was felt on the night of the 15th inst., and this has been followed by a constant series of slighter ones.

THE last number of *La Nuova Scienza* contains instructive papers on "Modern Italian Thought," on "Cosmic Evolution," and on the "German Pessimist Philosophy." The first of these papers deals with Prof. G. Sergi's "Origin of Psychic Phenomena" (Milan, 1885), which forms the fortieth volume of the Italian "International Scientific Library," and which contains a useful summary of the arguments of physiologists and psychologists on the genesis and nature of psychic force. Sergi contends that psychis is merely a function, or rather an implement of the body, analagous to the teeth, claws, and other offensive and defensive members. Against this materialistic conception Prof. Caporali, author of the paper in question, and editor of *La Nuova Scienza*, contends that pscyhis is inherent in all forms of matter, from the atom to the highest organisms, and that it is the cause, not the effect, of motion, that is, of all progress and evolution. It is an error to suppose that the organ originates the psychic function, for the function precedes the organ. The lowest organisms, such as the amœbæ, have no differentiated organs, yet they exercise psychic functions, as shown by O. Zacharia in his new work on "Organismen ohne Organe" (1885). Hence, to regard psychis as a mere function of the body, and introduce it later into the fully-developed nervous system as the product of the system, is neither philosophic nor scientific. The article on the German Pessimist school contains biographical notices and short summaries of the teachings of Schopenhauer, Von Hartmann, Geiger, Noiré, and other exponents of that philosophy. The *Nuova Scienza*, which continues to be conducted with remarkable learning and ability, deserves more general recognition than it appears to have yet received in this country.

TELEGRAPHS are extending with extraordinary rapidity over Southern China. At the present moment Pekin in the far north is connected by a direct line through Canton with Lungchow on the frontier of Tonquin, the extension from Canton to the latter place being made during the recent war, purely for military purposes. Thus we have one great line stretching through the Chinese Empire from north to south, and at the present moment an important line is being constructed along the southern borders of China through the provinces of Kwangtung, Kwangsi, and Yunnan. Starting from Nanking in Kwangsi, where it joins the Canton-Lungchow line, it will extend for nearly 600 miles to Mung-lih in South Yunnan, running for half the distance along the Yukiang, the name of the Canton river in its upper course. The work is being carried out by the Chinese themselves with the assistance of one European, and it is stated that during the recent war the Canton authorities equipped a complete field telegraph staff, the members of which were so thoroughly trained that they have been able to put up 35 miles of line in a single day for war purposes. Telegraphs have now secured a firm footing in China, and their extension over the whole country is a matter of time only, aided perhaps by political events. In the great movement towards a centralised Government now progressing in China the telegraph line will play a vital part, for it will utterly destroy the semi-independence of the provincial viceroys, hitherto secure in their remoteness from the seat of government.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus* ♀) from West Africa, presented by Miss Hodgson; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mrs. Berens; an Arabian Gazelle (*Gazella arabica* ♀) from Arabia, presented by Mr. John Patton; two Short-headed Phalangers (*Belideus breviceps* ♀ ♀) from Australia, presented by Mr. P. S. Abrahams, F.Z.S.; a Ring-necked Parrakeet (*Palæornis torquatus*) from India, presented by Mrs. Morgan; two Indian Cobras (*Naia tripudians*) from India, presented by Mr. W. G. Burrows; two European Tree Frogs (*Hyla arborea*), European, presented by Mrs. A. Bratton; two Catfish (*Amiurus catus*) from North America, presented by the National Fish Culture Association; two Mule Deer (*Cariacus macrotis* ♀ ♀) from North America, a Triton Cockatoo (*Cacatua triton*) from New Guinea, deposited; two Barbary Wild Sheep (*Ovis tragelaphus* ♂ ♀) from North Africa, four Spotted-billed Ducks (*Anas pœcilorhyncha* ♂ ♂ ♀ ♀) from India, purchased; a Sambur Deer (*Cervus aristotelis* ♀), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, NOVEMBER 22-28

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 22

Sun rises, 7h. 33m.; souths, 11h. 46m. 22·9s.; sets, 16h. 0m.; decl. on meridian, 20° 15′ S.: Sidereal Time at Sunset, 20h. 7m.

Moon (at Full) rises, 16h. 43m.; souths, 0h. 25m.*; sets, 8h. 14m.*; decl. on meridian, 17° 1′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	9 32	13 9	16 46	25 32 S.
Venus	11 28	15 8	18 48	25 13 S.
Mars	23 31*	6 31	13 31	10 54 N.
Jupiter	1 53	8 0	14 7	0 40 N.
Saturn	18 19*	2 27	10 35	22 21 N.

* Indicates that the rising is that of the preceding and the southing and setting those of the following day.

The Occultations of Stars and Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

Nov.	h.	
24	23	Saturn in conjunction with and 3° 59′ north of the Moon.

A special watch should be kept on November 27 and the days immediately preceding and following, in order to note whether there is any recurrence of the meteoric shower observed on November 27, 1872, and believed to be connected with Biela's comet. The radiant point is near γ Andromedæ.

CHEMICAL NOTES

In order to obtain constant temperatures easily maintained and completely under control, Messrs. Ramsay and Young (*C. S. Journal, Trans.*, 1885, 640) employ vapours of the following compounds, and alter the pressure to which each vapour is subjected: carbon disulphide, ethyl alcohol, chlorobenzene, bromobenzene, aniline, methyl salicylate, bromonaphthalene, and mercury. By the use of the vapours of these bodies at various pressures, any desired temperature between that of the atmosphere and 360° can be easily obtained. The authors have very carefully determined the vapour-pressures of these compounds for a large range of temperature. The methods of experiment are fully described, and the results are presented in the form of tables, which must prove of much service to those chemists and physicists who have occasion to raise pieces of apparatus to a known temperature, to vary that temperature if required, or to keep it perfectly constant for an indefinite period.

As was noticed in these columns some time ago, Dixon has recently proved that a mixture of perfectly dry carbon monoxide and oxygen is not exploded by the passage of electric sparks; but that the presence of a minute quantity of water suffices to determine the combination of the gases. Dixon supposed that the action of the water was as represented in the following two equations:—

$$(1)\ CO + H_2O = CO_2 + H_2,$$
$$(2)\ 2H_2 + O_2 = 2H_2O.$$

Now Traube (*Ber.* 18, 1890) has shown that carbon monoxide does not decompose water in complete absence of air or oxygen, even at very high temperatures; he has also shown that when moist carbon monoxide and oxygen are exploded together, hydrogen peroxide is an invariable product. Traube suggests that the following three changes probably occur during the explosion in question:—

$$(1)\ CO + 2H_2O + O_2 = CO(OH)_2 + H_2O_2.$$
$$(2)\ CO + H_2O_2 = CO(OH)_2.$$
$$(3)\ 2CO(OH)_2 = 2CO_2 + 2H_2O.$$

When hydrogen is burnt in moist oxygen, hydrogen peroxide is always produced, according to Traube. Whether a perfectly dry mixture of hydrogen and oxygen could or could not be exploded by electric sparks cannot be regarded as settled; Traube thinks that such a mixture would prove to be non-explosible. He regards the mutual action of hydrogen, oxygen and water as in all respects comparable with that of carbon monoxide, oxygen, and water, or with that of zinc, lead, and some other metals, oxygen, and water. The changes which occur in the explosion of moist hydrogen and oxygen are formulated by Traube thus:—

$$(1)\ H_2 + 2H_2O + O_2 = 2H_2O + H_2O_2.$$
$$(2)\ H_2O_2 + H_2 = 2H_2O.$$

The occurrence of the second part of this reaction has been experimentally demonstrated by Traube.

In continuing his experiments on nitrification, Warington (*C.S. Journal, Trans.* 1885, 758) has shown that the limit of concentration (about 12 per cent.) beyond which urine ceases to be nitrifiable under ordinary conditions may be largely extended by adding gypsum to the liquid. A solution containing 50 per cent. of urine, and 22 milligrams of gypsum for every c.c. of urine, began to nitrify after about five months; solutions containing 15, 20, and 30 per cent. of urine began to nitrify after the lapse of 53, 68, and 78 days respectively. The gypsum prevents the accumulation of ammonium carbonate in the liquid.

J. H. van't Hoff describes (*Berichte*, xviii. 2088) experiments on phenomena, analogous to those exhibited by gases at their "critical points," occurring during chemical decomposition. Phosphonium chloride, PH_4Cl, which melts at 25°, was heated to 50°-51° at a pressure of 80-90 atmospheres in a Cailletet's apparatus; under these conditions the line of separation between liquid and vapour disappeared, and, on cooling, the formation of nebulous streaks became plainly visible. It is well known that the vapour obtained by heating PH_4Cl under ordinary conditions consists of $PH_3 + HCl$; it is not possible to say to what extent the melted substance in van't Hoff's experiment consisted of a compound of PH_3 and HCl, and the gaseous part consisted of a mixture of these constituents, yet it seems certain that, when PH_4Cl, a compound which is chemically decomposed when vaporised, is heated to 50° under a pressure of 80-90 atmospheres, there exists identity between the vapour and the condensed portion of the body.

La Coste describes (*Berichte*, xviii. 2122) a modification of V. Meyer's apparatus whereby the densities of easily decomposed compounds may be determined at low temperatures under small pressures.

GEOGRAPHICAL NOTES

A catalogue of the printed maps, plans, and charts in the British Museum has been prepared by Prof. Douglas, and will be issued in two large volumes. It represents the contents of the manuscript catalogue in 323 volumes, the catalogue of the maps and plans in the Royal Library in two printed volumes, and the manuscript catalogue of charts in the same library. The original manuscript catalogue was made under the superintendence of Mr. Major, late Keeper of the Department of Maps. The orthography adopted in the present catalogue is that used in Keith Johnston's "General Dictionary of Geography," with the exception of India, for which Hunter's "Gazetteer" has been taken as a guide. The utility of this catalogue to the geographical student will be found in the comparatively simple alphabetical arrangements for the headings of countries and places, combined with the names of geographical writers, which last often serve as short cuts to any particular atlas or map. Thus, under the head of "Ptolemy," the pillar and foundation of ancient geography, there are seventy-four entries referring to the various editions and copies of his "Geographica." Turning to the names of the fathers of modern geography, Ortelius and Mercator, we find under the former twenty-nine entries describing the various copies and editions of his "Theatrum orbis Terrarum." The geographical labours of his contemporary and friend, Mercator, will be best realised by a reference to the heading "World: Atlas: Modern," p. 4491, where will be found probably the most complete list of Mercator's atlases extant, ranging from 1495 to 1636.

AT the meeting of the Geographical Society of Paris on the 6th instant, M. Germain, who presided, pronounced a eulogium on Milne-Edwards. M. Duveyrier called attention to a report addressed to the Spanish Government by Capt. Bonelli, relative to the Spanish possessions on the West Coast of Africa, according to which it appeared that the writer claimed on behalf of Spain nearly a hundred kilometres of the coast belonging to the French in Senegal. A letter was read describing the departure from Buenos Ayres of M. Thouar on a new expedition to complete his work on the Pilcomayo. A note was read from M. Venukoff on the recent incidents of Russian geographical exploration. M. Chaffaujon described his late explorations in the basin of the Orinoco, to which we have already made frequent reference.

THE current number of *Petermann's Mittheilungen* has for its first article a lengthy communication by Dr. Theodor Fischer on the development of coasts. His conclusion is as follows:—Wherever the sea by breakers and currents has exercised a preponderating influence on the form and development of coasts, whether flat or precipitous, the line of coast takes the form of a succession of arcs, in the case of steep coasts with a short, and of flat coasts with a long, radius; where the coasts exhibit other features than these, although the action of the sea be not wholly excluded, yet other causes, especially tectonic alterations in the surface and movements of the earth's crust, are more powerful or are very recent. Herr Langhaus gives a map of the Cameroon Mountains, with an accompanying description, containing a short sketch of recent exploration in the region. Dr. Boas writes on the topography of Hudson's Bay and Hudson's Straits, with a map; and Herr Wichmann describes the new republic in South Africa, also with a small but remarkably clear map by Dr. Havernick. The usual geographical and critical notes and lists conclude the number.

M. EUGÈNE AUBERT has been charged by the Ministry of Public Instruction with a scientific mission to the basin of the Amazon.

BEES AND OTHER HOARDING INSECTS[1]

Their Specialisation into Females, Males, and Workers

IN discussing the differentiation of bees into females, males, and workers, I shall have no need to call your attention to any new discoveries in the world of wonders among those minute creatures that we have had with us for all ages, and whose life we are just now beginning faintly to understand. My illustrations will be drawn mainly from other orders, in which it will be impossible for me to make a mistake without its being readily seen by some of the general public as well as the specialists.

The limits of this paper will not permit elaborate definitions, or fine discriminations, and I have therefore to ask that you will kindly make your own definitions, taking care to give to my words in general the narrowest sense compatible with the use to which I apply them.

From the creatures and the plants, that man has domesticated for his use, we have learned nearly all of the lessons in heredity, which we have no good reason to unlearn, and my first illustration shall be from one of these, the barn yard fowl.

If we mate a Black Spanish fowl with a Buff Cochin, and hatch out the eggs as the bees do theirs, in an incubator, till we have a hundred chicks, among these we shall find a very great diversity. Some when fully grown will be nearly, if not quite, as heavy as the Buff Cochin, and some will weigh little, if any, more than the Black Spanish. Their respective weights will probably vary between those natural to their sex in the two varieties to which their progenitors belong, but much the larger number will be very nearly half way between. And as colour is not necessarily correlated with weight, it is quite possible that the heaviest chick will be the blackest; that is to say, that he may take his colour almost entirely from one parent, and his weight and form from the other. In colour every one of the hundred chicks will, when fully grown, be in some degree distinguished from every other; and if we take colour, size and form together for our guide, there will not be one among the whole number that we cannot readily distinguish from every other. Now this particular cross from the great difference in size, form and colour of the parent stock enables us to see very clearly a fact which the closest and most careful investigation shows to be a general law. It is this:

All offspring are variable by heredity. And under some circumstances the variations are wide.

Nearly every youth, who has amused himself with an aquarium, knows that he can dwarf his fish if he chooses to do so. Other things being equal, the weight of a fish depends upon the amount of food it is allowed to consume. This variability is so great among fishes, that of two as nearly alike as possible, either one may be fed so that he shall exceed a pound in weight, before the other, receiving very little food, shall turn the scale at an ounce.

Thus insufficiency of food affects the development of all organs. All breeders of animals have some knowledge of this fact as applied to their own business, and of which our fish merely affords a striking example. It is an inevitable deduction, that when the food is of the general quality which is suitable for the due nourishment of all the organs but is insufficient in amount, the stronger organs, if such there be, will take more than their share, and the weaker organs will go to the wall. From this matter of food supply we have a general law, which may be stated as follows:

Living creatures are variable from the amount and quality of their food. And among some orders the limits of this variation are wide.

It is scarcely necessary for me to go into the fact that the insects, being exposed to more extreme vicissitudes than the larger orders of animal life, are much more variable in almost every respect. It will be interesting, however, and it may be instructive in the line of our inquiry, to point out some powers of variation in sex in a very common plant, which, while they are very much greater than those of the bee, have some points of striking resemblance.

Indian corn is pictured to the unobserving mind as a plant bearing something good to eat at the side and a tassle on the top. The botanist tells us that the tassle on the top is a male plant, that at the side is a female plant or perhaps more than one, that all these are joined upon one stalk, and that the something good to eat is the product of the female plant, fertilized by the pollen of the male. All this is fact as far as it goes; but it gives us no conception of the whole truth.

On going into the field in bloom we find that nearly all of the stalks have tassels on the top; they are male plants. In a good field we shall find perhaps half of them with reproductive females at the side, say two good ears of corn to a hill. There are, therefore, nearly twice as many perfect males as there are of perfect females. We find also that the undeveloped females are very numerous—from one to half a dozen on a stalk. And a close examination shows that the number of females that become developed is almost entirely a matter of food. Such an investigation shows also some plants bearing only a female on the stalk and some that are entirely undeveloped in both sexes.

Thus in our field of Indian corn we have male stalks, male and female stalks, female stalks, neuter stalks. And the stalks that bear developed male and developed female individuals all have (*a*) a male individual on the top, (*b*) one, two, or three females at the side, (*c*) one to six undeveloped females at the side, and possibly with, possibly instead of these (*c*) they may have (*d*) one to half a dozen buds and germs of females at the side.

If, when the corn is ripe, we go with the farmer and gather a basketful, we shall invariably find that on each ear there are kernels less perfectly developed than others, and we shall have every reason to believe that in the basketful there are some kernels that could not reproduce, that some kernels would reproduce but would, under the most favourable circumstances, give but imperfect offspring, and that there would be a very wide range in the degrees of the imperfection of the plants produced from these imperfect kernels.

As a matter of fact, the farmer in planting, selects with care the most perfect ears, and the most perfect parts only of the ears so selected, and yet we have the males, the females, and the neuters or the undeveloped for the result as I have described them.

Indian corn is so extremely variable in this matter of sex, that careful experimenting in this direction would be likely to give most interesting results in a single lifetime.

[1] Read before the Brooklyn Entomological Society, December 29, 1884, by Edwin A. Curley.

Having now illustrated some principles of variability, and given some idea of the extent to which it may go, under our own observation, we must deal with the question before us by way of hypothesis.

Let us suppose a primitive or typical Bee among the honey-seeking insects of early days. She is necessarily a creature having such attributes as are common to all species of bees which are her offspring, but in many respects she is very unlike our Hive Bee of to-day. We see her at a time when this typical species has already learned the wonderful lesson of thrift. She stores honey in times of plenty to provide for times of want. She is feeding her offspring from her stores. As the keen competition of life goes on, she must provide for the wants of her offspring for an ever-increasing period, and, as her powers in this respect are taxed to the utmost, her powers of reproduction are of necessity diminished; she produces some imperfect eggs, and she produces fewer eggs. Still, the vast majority of her offspring perish, either for lack of sufficient food or as prey to natural enemies before their power of self-defence are sufficiently developed for successful flight or resistance.

It is quite reasonable to suppose that the bee has been subjected to such vicissitudes as these. The extraordinary differences in the sizes of the various living species of bees would indicate the truth of the theory of insufficient food as far as we have yet followed it. If we have a species of bee only one-eighth of an inch in length while some others are an inch and a quarter in length and stout in proportion, it will take one thousand (1000) of these Lilliputian bees to weigh as much as a single specimen of one of these largest species. Is it not most reasonable to suppose that this tremendous variation in size is chiefly due to the matter of food supply, as is the well-known fact in the very large variation we can thus make in the size of an individual fish?

Now when the food supply is so very scant that the size of the offspring is necessarily much dwarfed, evidently the weakest will die in the process of rearing; evidently also the mother-bee whose reproductive powers are the weakest as to the number of offspring, and whose maternal instincts are the strongest, that is to say, the one that lays the fewest eggs and takes the best care of her young, will best succeed.

If any broods of young perish altogether from famine, it will be those that are so numerous as entirely to overtax the powers of the mother-bee in feeding them. Thus we gradually approach a time when the care of the mother-bee extends to a period in the life of the offspring when they appreciate and respond to her affection. The offspring are still numerous and the struggle for existence is severe. The food supply is sufficient to bring the young to that point in existence when they are capable of applying with some prospect of success the instinct, that is to say, the congenital knowledge, inherited from the mother. And as the mother-bee continues after this period to help them in their struggle for existence, they see and understand her assistance, and they necessarily respond to her affection. Here is definitely established filial love, in response to maternal affection, and it is necessary that this filial love should be established in strength even in this little insect before it is possible that the specialization under consideration shall commence. It must not be supposed that the size of these tiny creatures renders them incapable of this strong feeling—we must in this respect as in others go by the evidence of our senses and the necessities of the case. Without strong affection the whole life of these bees is quite inexplicable, while with it their conduct is the natural outcome of a certain amount of intelligence applied to certain conditions of existence.

Among all creatures nursed with a mother's care, filial love grows stronger and stronger according to the capacity and circumstances of the offspring and the strength of that affection which calls it forth. But when the time for mating approaches the young seek other relationships and so far as it is incompatible with these does filial love decay.

But what happens if the young are by nature incapacitated for these other relationships?

Then filial love necessarily grows with the individual and strengthens with her strength.

The mating instinct may be almost or wholly lacking; and, if wholly lacking, then all of that part of the highly nervous organization inherited from the mother that is devoted to the affections will have no other outlet than in filial love.

The common life around us, and man himself will perhaps afford us some partial illustrations of this necessary law. The best illustration outside of the insect world is one of which the facts may be easily ascertained by any person who will make the inquiry.

The breeding of mules is an important industry. The horse and the ass are capable of strong affection, but their colts seldom develope a filial love which has a controlling influence on their adult life.

But the mule, the hybrid between the male ass and the female horse, except in very rare instances, is congenitally incapable of reproducing its kind. It has more or less of the instinct for mating, but it necessarily does not have the strong sexual passion of a perfect equine animal. Its love for its mother however amounts to a master passion; it is not spasmodical, but it is intense and it continues as long as there is an opportunity of showing it. It is capable of transfer to another object and those who breed mules in large numbers take a useful, instructive, and amusing advantage of this fact.

When the young mules are weaned, the mothers are withdrawn from their company, and one, otherwise worthless old mare is substituted for many mothers. The poor young things turn to the good-natured old mare as to a very goddess; while she receives their worship with the equanimity of her sex, never hinting in the mildest terms that it is an idolatry that should be abated. As the dilapidated goddess herself may be depended upon for her staid qualities, it follows that her worshippers are thereby kept out of mischief. And the poor mule is not a backslider, it is always a consistent worshipper.

I have stated that filial love is absolutely necessary to the specialisation under consideration. It should be added that it must be intense in its character and capable of replacing to a large extent the maternal instinct of the perfect creature.

From the fact that insufficiency of food would affect the growth of all organs we deduce the further fact that it would affect weak organs the most, giving those not congenitally perfect an irregular development. It follows also that if a very young animal congenitally perfect, receives for a long period only sufficient food to sustain life, the organs not vital will be more or less dwarfed in their proportions, as compared to the vital organs.

For here the law of parsimony is absolute. The vital organs *must* receive a certain supply, or the life perishes. The non-vital organs make no such imperative demand, and they consequently get less in proportion. And an organ that is entirely useless to the life of the individual, would under such circumstances receive no nourishment whatever; excepting only as it is correlated to the organs that are useful or vital. The reproductive organs of the young of all species are entirely useless to the life of the individual; their powers are latent, and, excepting as they are correlated to other organs, they make no demand for nourishment. Starvation must therefore dwarf the reproductive organs of very young individuals, in proportion to those which are very important, or absolutely necessary to life. In plants this fact is constantly shown all around us and our maize is a striking example.

The reproductive powers of swine are very great. But a young pig that is half-starved will not only have its reproductive powers very much retarded in their growth, it will have them diminished in their ultimate strength. This is a matter in which general observation furnishes the proof. I have not asked fish-culturists the question but I am absolutely certain that, other things being equal, the number of fish-eggs will depend upon the size and thrift of the individual, and these, other things being equal, depend upon the question of food.

It is easy to imagine a possible case among the vertebrates or even the mammals in which a perfectly normal organism by long continued insufficiency of food, is allowed a slow development of those organs that are absolutely necessary for its life, and of the others most nearly correlated to these, while the organs of reproduction, in the incipient or undeveloped stage in which they were when starvation commenced, still remain till they become fixed and immutable, notwithstanding any abundance of food that may be given at a later period of life.

Let us now go back to the variability of eggs as shown by our hundred chicks or the variability of seeds as shown by our ears of corn. This variability is variability of the germs, and this is congenital variability. This variability as shown in the hundred chicks gives us from three to six pounds for their adult weight and they all differ in colour, form, or both.

We take no account at present of the fact that our primitive bee as shown by her offspring of to-day was far more variable than fowls, but we note that she was a hoarding insect, gathering with great care and industry in good times food for times of scarcity; that she supplied her young from her stores; and that they responded to her maternal cares with filial affection.

We left her at a time when the struggle for existence was keen and some of her offspring starved through no fault of her own. She was exhausted with a constant search for food and the cares of a numerous and starving family.

This necessarily involved the fact that her reproductive system was quite out of balance, she was incapable of producing as many eggs as her progenitors, and many of those that she did produce were imperfect.

Of these imperfect eggs some addled and some hatched out imperfect offspring.

At this point we proceed to inquire into the nature of the imperfections of the offspring.

There would probably be quite a variety in these defects. One might be wanting in legs, another deficient in wings, another insane, another deaf, another possibly congenitally blind, or perhaps wanting in that sense, whatever it is, by which ants and bees intelligently converse with their fellows.

All of these and many other congenital defects are possible and even probable, because we see them in other and the least changeable orders and species of creatures.

But the greatest in number of all the very important defects would be defects of the reproductive organs; because they are the organs in the mother which have been most affected by her unfortunate environment.

Under these circumstances, what must become of all the imperfect offspring in a sharp struggle for existence?

Manifestly all wanting in legs, or wings, or eyes, or in any organs necessary for quick and intelligent movements in attacking or resisting enemies, or in collecting food, must die at an early age, notwithstanding any possible care of the mother.

Manifestly none of those defective in the reproductive organs would so die, unless they were also defective in some other particular, unless indeed the struggle became so keen that perfect and imperfect went to the wall together.

Manifestly also these insects thus congenitally imperfect in the reproductive organs would have a great advantage over all others in the struggle for existence, *from the time at which the reproductive period in those others commenced.*

If altogether incapable of reproduction, they would have vitality enough for themselves and a surplus to expend.

The energy inherited from the hardworking progenitors would be too great for idleness. The surplus must be expended at the dictates of love or hate. Hate, beyond that healthy indignation at attack or imposition which is necessary to self-protection, is unnatural to such beings.[1] But they have one to love, and that is the mother. The perfect offspring depart to reproduce their kind, and the one, two, three, or the dozen of the imperfect ones, stay behind with the mother bee, or if she dies they transfer their affection to some one of their perfect sisters.

Now another hoard of honey must be gathered, and another lot of eggs laid, hatched out and cared for. The female bee works industriously and, true to her instinct, denies herself of necessary food that she may lay by the more for her future offspring.

And now these creatures, happy in their deprivation, capable of supplying their own wants with ease, insist on gathering food for the mother-bee. She takes it with eagerness, tastes and stores it away. And after the young are hatched out, the like attempt to feed the mother-bee results in feeding them. Thus this family have for a time a great advantage in the struggle for existence and there is a perfectly adequate motive for the conduct of the kind little creatures who minister to the wants of the mother-bee.

Still this happy family is not precisely the foundation of our modern bee-hive; it is really too affluent for complete success.

The mother-bee, no longer overworked, recovers her health and unfortunately lays perfect eggs; with the help of the nursemaids she rears her young without overtaxing her powers. Her family and any others like it have very decided advantages over the old type, to which nevertheless they inevitably revert, to fall into a state of starvation as before; for, in this family, the nursemaids have, and can have, no probable successors while there is plenty to eat.

If this happens to one family of bees, it will probably happen to many families. The temporary affluence of one family caused by the presence of the helpers will itself increase the depth of poverty in the neighbouring families, and this poverty will give them helpers in undeveloped bees in the next generation, by which in turn they will be raised to affluence. Thus there will be alternating generations of bees—that is to say, generations with helpers, followed by generations without them.

Among those that go forth from the mother-nest to find mates and rear families of their own are some that are congenitally weak in the reproductive organs. The majority of these meet with sound mates and the variation dies out. But some individuals thus congenitally imperfect meet with like mates. The congenital weakness of the reproductive organs is intensified in the offspring. The majority are perhaps so imperfect as not to be able to reproduce their kind. Any of these that reach maturity will be glad helpers of the mother-bee.

Their less imperfect brothers and sisters are defective in many degrees. The offspring of one never reach maturity. Those of another nearly all thrive and there are a dozen reproductive females among them.

In their migrations at swarming time these bees sometimes become established near less affluent families, congenitally perfect, and are sometimes crossed with them.

Here we have the bees in a condition of the greatest variability as to reproductive powers, but all of those that are getting on well in the world have among their offspring some that cannot reproduce, and helpers are consequently numerous.

About this time the paupers are established as a distinct variety. Sick and discouraged with the unsuccessful battle of life, they are more or less tolerated in the affluent families of their neighbours. But when they have recovered their bodily strength, they have not also regained their mental balance. They have become accustomed to a life of tolerated dependence; so they live in the nest and lay eggs to be reared by their industrious neighbours. Sometimes the imposition becomes too great for good nature to stand and there may be a terrible slaughter of the innocent paupers and their offspring. The ones however that most nearly resemble the useful members of the community escape destruction and thus are established the Cuckoo-Bees, their simulation of virtue being ever the closer as indignation increases at their vice.

The varieties become extremely numerous; many of them however becoming rapidly extinct. At first in all families where there are helpers there are almost or perhaps quite as many undeveloped males; but this being for bees a hurtful variation the tendency of natural selection is to their diminution. On the whole those families are the most successful in which there are the largest number of undeveloped females.

All this time experience is being gathered in the mothers and differentiated and stored in their systems, to re-appear as instinct and intelligence in the offspring.

Sometimes the most affluent families come to want, and perfect females are dwarfed in their reproductive organs by scarcity of food and are only capable of being helpers.

From all this diversity there is at last a type evolved which is on the whole the best for the majority of the bees. This type is one involving a degree of imperfection in the reproductive organs of all offspring unless highly stimulating food in large quantity is supplied from a very early stage of growth. Thus the normal product is simply a helper and the number of males and females in proportion to the number of helpers and the food supply is a matter entirely under the control, not of chance nor of the mother, but of the community. This then, I think, is the foundation of the Hive-Bee family, the highest type of the flying Hymenoptera.

As instinct enlarges and intelligence increases, the helpers take more and more upon themselves the care of the household. They become pre-eminently the workers, and their officious interference is continually stopping the mother-bee's toil, and stuffing her with the best food they can obtain. She gives herself up more and more exclusively to the work of reproduction, and her powers increase till she becomes capable of changing food into eggs and individually starting a hundred thousand existences in her single lifetime.

Between this highest type of the bee and the lowest, we find several hundred varieties all capable of explanation, either as progressive or retrogressive developments from our primitive bee. Many of them are highly specialised in their social habits, and it seems to me that all those that have two fully developed sexes and one or more undeveloped sexes, must necessarily have

[1] Lubbock's instances of ants attacking strangers and not rescuing friends by no means demonstrates the opposite of this proposition.

thrift, intelligence and filial love as the foundation without which it is impossible that such creatures should of themselves build up such a singular condition.

It seems to me that hunger, something approaching starvation, is necessary as a beginning of the specialisation. Now we all know that from their capacity to increase with enormous rapidity some insects are subject to great vicissitudes in the matter of food. The locusts, for instance, increase in numbers till, having eaten everything in their native habitat, they leave it in dense masses that obscure the heavens and which devastate vast regions. Of the next brood, immensely more vast in numbers than even these, comparatively a small remnant reach maturity, and scarcely any reproduce their kind. The race grows up again from the few starved individuals too weak to leave the old habitat and of which a few manage to survive long enough to lay some eggs. Those doubtless produce many imperfect insects, but these specialisations are not useful to the race in this case, and they cannot survive. I think it likely, however, that man could specialise locusts and many other insects in this way without difficulty. I think it likely that he could with great care so specialise fish and possibly fowls and with great patience and much difficulty some of the mammals. I think also that if mules were from a thrifty hoarding stock like squirrels they would be in the habit of feeding the old mare as the workers feed the mother-bee. But while it may be allowable to mention these as interesting possibilities I do not propose to discuss them in this paper.

There is another element which is, I think, very important in fixing the definite type of the workers, and which I had intended to discuss. But while I think that element important in the bee and perhaps absolutely necessary for the still higher specialisation of the ant, I think also that a permanent body of workers is necessarily evolved from the conditions which I have assumed as natural and proper to the primitive bee.

To recapitulate in few words:

I presuppose a primitive bee fertile and affectionate, hoarding and intelligent.

I show that great want will necessarily diminish the number of her eggs.

That it will render some eggs imperfect by deranging the reproductive organs of the mother.

That consequently some of the offspring will be defective in the reproducing organs.

That while other imperfect bees will generally die before maturity, those imperfect only in the reproductive organs will live if the perfect offspring live.

That some of these being incapable of mating, will not go away for that purpose, but will stay with the mother-bee.

That, having surplus energy to expend, they will use it in accordance with the instinct of the race in gathering and storing food.

That the surplus food will be utilised by the mother-bee, and that therefore this family will be affluent.

That, being affluent, the formerly overtaxed mother will recover her health, and that her offspring will thereafter be perfect.

That consequently these nursemaid-bees will have no successors, and the family will therefore be again reduced to want.

That some bees of the same hatch with the nursemaids will be congenitally imperfect, notwithstanding that they leave the mother and find mates.

That the offspring of congenitally imperfect bees will be extremely variable.

That some of this offspring will be unable to reproduce and that they will remain with the mother-bee as nursemaids or helpers.

That these helpers from the congenital imperfections of their mothers will have successors; substantially as is seen among the hive-bees and the humble-bees of the present day, and

That the variation thus started will eventually be reduced to a definity type or to definite types—by the survival of the fittest.

That whatever other circumstances may aid in producing the result in question, this is sufficient of itself to account for the specialisation of the bee and the ant into females, males and workers.

SCIENCE IN FRENCH COCHIN CHINA

WE have already referred to an official publication of the French Colonial Government in Saigon, entitled *Excursions et Reconnaissances*, which appears every two months, and is wholly devoted to recording the investigations made by French officials in French Cochin China and the neighbouring semi-independent and independent States. The course and results of the numerous scientific missions despatched to these regions by the Ministers of Education and the Colonies, as well as the travels and researches of private individuals, are published in this periodical; and as there are six numbers published annually, of about 200 large octavo pages each, it will readily be perceived, apart altogether from the dearth of information, other than political, with regard to the great Indo-Chinese peninsula, that these volumes form a mine of knowledge of the most authentic and trustworthy description, for the writers are for the most part men who have been specially selected in France to study the subjects with which they deal. Unfortunately, however, the publication is but little known in this country, no copy being obtainable in some of our largest official libraries. As it is on sale in Saigon, and doubtless also in Paris, there is no reason why a periodical so valuable should not be made accessible to English students.

We have before us the three last numbers, and from them it is possible to obtain an idea of the scientific work which the French are performing in their new possessions. No department of research escapes their attention, and they are indefatigable in studying the country and people for whose welfare they have now become responsible. In one respect these volumes resemble those of many learned societies in India and elsewhere: they are extremely varied in their contents. Shafts have been driven in all directions, and the result is here; but when we recollect the short period that the French have been even at Saigon, the still shorter period that they have been able to travel in the interior, it will be apparent that no merely private society could accomplish the work done here. The traveller in most parts of Cochin China still requires a guard of twenty or thirty *tirailleurs*, which can only be provided by the Government. Again, few private persons, however enthusiastic, could afford to spend several years travelling over every part of Cochin China in search of ancient inscriptions, as M. Aymonier has done. Such work as this could, under the circumstances, only be performed with the assistance of Government; and it is greatly to the credit of the French Government that amongst its responsibilities in connection with colonies in the East, it recognises that of thoroughly investigating in a scientific manner the people and territories around them. It has often been said that the French are more sympathetic rulers of subject races than the English, and that they succeed sooner in gaining their affection; whether this be true or not, it is certain that they go the right way to rule properly, by setting themselves at the outset to comprehend what manner of people and of country it is that they are called upon to rule. Science, at any rate, gains by the French practice a consideration which is not very often present to the minds of our colonial rulers.

Geography naturally plays a considerable part in the *Excursions et Reconnaissances*, for a great part of Cochin China is still a *terra incognita*. For a like reason there is much that is specially ethnological. Thus, in the numbers before us we have two papers on the Moïs tribes: one by M. Nouet, recounting a journey amongst the Moïs on the north-eastern frontier; the other, by M. Humann, on the independent Moïs. In the first these curious people are described as slothful and careless, knowing nothing of money, wandering about from place to place in search of subsistence, without any industry beyond producing articles which are absolutely necessary, and always hungry. They are excessively timid, flying into the forest on the approach of a stranger; they have no writing, and appear to have no religion either; they bury and burn the dead, but there are no subsequent ceremonies in connection with the departed. Even those within French territory lead a savage life; their existence is described as, not dying of hunger, rather than positive living. But the race is disappearing slowly from misery and disease; the prohibition against burning the forests is said to bear hardly on them, as it is the only method they know for clearing patches for the cultivation of their rice. The independent tribes, described by M. Humann, are braver than those which are found further south; they can work in iron, and appear more provident and less nomadic. But they live amongst the mountains, whither they have fled before the Annamites on one side and the Siamese on the other.

Dr. Tirant contributes a very long paper, extending over the last three numbers, on the reptiles of Cochin China and Cambodia. It does not profess to be complete, for an exhaustive study of the subject would require collections and books not to be obtained at Saigon. That it must be tolerably full, however, appears from the list of serpents, of which there are 87 in all, 17 being poisonous, the rest harmless. The scientific name, the Annamite and Cambodian names, are given in each case.

The inscriptions scattered all over Cambodia, which, like the great ruins of Angkor, have come down from an earlier civilisation which has otherwise disappeared, have attracted much attention, and have now apparently reached a stage in which scholars are violently quarrelling about them. Papers on them, generally accompanied by copies of the inscriptions, appear in every number of the periodical. M. Aymonier was specially sent out from France to study them, and in less than three years he succeeded in obtaining a *corpus* of about 350 inscriptions. These are in many languages, the principal, however, being in Khmer, or ancient Cambodian; and their examination has thrown much light on the history of Cambodia in ancient times, and possibly on the ethnological problems of the Indo-Chinese peninsula. The general result of the investigation so far, represents the distribution of the inhabitants of the southern part of the peninsula in the first centuries of the Christian era as follows:—The Annamites were still confined to Tonquin, while the Chams occupied the coast of the present Annam; tribes more or less numerous called Chongs, Kouis, Samre, &c., occupied the present Cambodia and Southern Laos. Probably their social state was more advanced than that of the tribes still existing between the valley of the Meikong and the coast of Annam. The Laotian people spread along the valley of the Meikong from Luang Prabang in Siam to Lokhon, while the Siamese were scattered about in principalities in the centre of the country now occupied by them. There existed a primitive religion amongst all these tribes: in April they rendered homage to the spirits of the high places, and in October they offered of the fruits of the earth to the *manes* of their ancestors. They knew of the use of iron and made arms and tools for themselves, and they cultivated rice. Then came Indian traders, who penetrated by the Meikong River, founded small colonies, and reduced some of the natives to slavery. They established independent states, and from them we get the name Cambodia, originally a title of honour. Thus the present population of Cochin China is the result of two totally distinct races and civilisations—Indian and the aboriginal native. The inscriptions give the history of the Khmer dynasty down to the twelfth century.

M. Landes writes on the folk-lore of the Annamites, while M. Aymonier has another long paper entitled "Notes on the Laos," being a series of observations made during journeys in the Laos country, which he has not been able to work up into a connected paper on this curious people. They embrace every conceivable subject relating to the Laos: the geography of the country, their ethnological features, customs, rites. There are up to the last issue seventy-nine of these notes, referring to as many different points connected with these tribes.

A lengthy report by Dr. Burck, Director of the Botanical Garden at Buitenzorg, in Java, is printed. It contains an account of his exploration in the highlands behind Padang, on the west coast of Sumatra, in search of the trees which produce guttapercha. The present state of the subject is this: Specimens of guttapercha are found in considerable quantities in trade, but it is impossible with our present knowledge to determine the botanical origin of a single one of these specimens. The *Dichopsis gutta* (Benth.), the *Isonandra gutta* of Hooker, is the only species of tree producing guttapercha of which botanical specimens have been sent to Europe. But it has never been exactly and completely described, for no man of science has seen the fruit or seeds in their maturity. No one can at present affirm with certainty the origin of such or such a kind of guttapercha in trade. Dr. Burck maintains that the tree has never been found at Singapore and that since the disappearance of the forests there no one can affirm that the *Dichopsis gutta* can be found in its wild state. The paper is of considerable length and the writer disputes certain statements in the Kew reports with reference to the trees producing guttapercha and the places where they are found. An account of a journey in Siam and a translation of a long Tonquinese poem with copious explanatory notes and an excursus on Annamite literature are the remaining papers of these three numbers, the product of six months' work. At this rate the eastern part of the Indo-Chinese peninsula cannot long remain unknown to Europe.

Since the above was in type we have received the succeeding number (vol. ix. No. 22) of the periodical here referred to. It contains a report from M. Aymonier on a further journey of his in search of inscriptions, and describing in some detail the tribe of Chams in Cambodia. He promises a complete work later on this tribe in the province of Binthuan, which have been almost wholly unknown hitherto. The same writer concludes his valuable notes on the Laos, the present instalment dealing with the Kouis, the Khmers, and the province of Korat. These notes occupy more than half the whole number, and, in the present state of our knowledge of the Laos tribes, are simply invaluable, supplying as they do the results of long and close observation on the part of the only European traveller who has yet had an opportunity of living and travelling amongst them. M. Baux has a short encyclopædia sort of article on tea, which is of no especial note. M. Landes continues his folk-lore of Annamites, under the title "Contes et Légendes Annamites." So far he has given fifty popular tales and fables, in which we find many old friends. Androcles and the lion reappear, for example, as the midwife and the tigress, the reward being a pig caught by the latter and carried as a present to the woman. Dr. Tirant, having concluded his study of the reptiles, commences in this number a paper on the fishes of Lower Cochin-China and Cambodia. Fishes play here a preponderating zoological *rôle*; Southern Indo-China forms an ichthyological province closely allied with Malayasia; Lower Cochin-China in particular has curious affinities in this respect with Borneo. The present number contains only the first instalment of Dr. Tirant's "Notes," as he modestly styles a paper of great research and investigation.

ON THE MEASUREMENT OF MOVEMENTS OF THE EARTH, WITH REFERENCE TO PROPOSED EARTHQUAKE-OBSERVATIONS ON BEN NEVIS[1]

MEASUREMENTS of earth-movements are of two distinct types. In one type the thing measured is the displacement, or one or more components of the displacement, of a point on the earth's surface. For this purpose the mechanical problem is to obtain a *steady point*, to be used as an origin of reference, and this is effected by making use of the resistance which a mass opposes to any change of motion. This may be called the *Inertia* method of observing earth-movements. It is applicable to ordinary earthquakes, and also to the more minute earth-tremors which would pass unnoticed if instrumental means of detecting their presence were not employed. The steady point is to be obtained by suspending a heavy mass (with one, two, or three degrees of freedom) in such a manner that its equilibrium is very nearly neutral. Any moderately sudden displacement of the ground in the direction in which the mass has freedom to move leaves the mass almost undisturbed, and the displacement of the ground is therefore easily measured or recorded by a suitable autographic arrangement, which must be so designed as to introduce exceedingly little friction.

The second type of measurement is that in which the thing measured is any change in the inclination of the surface of the ground relatively to the vertical. Movements of this class have been examined by d'Abbadie and Plantamour, and also by G. H. and H. Darwin, who have given the results of their observations to the British Association in two reports on the lunar disturbance of gravity (1882-3). Perhaps the most convenient name for these movements is "earth-tiltings." They are measured by what may be called the *Equilibrium* method. A pendulum, suspended in a viscous fluid, is employed to show, by its equilibrium position, the true direction of the vertical, and that is compared with the direction of a line which is fixed relatively to the surface of the ground; or, instead of a pendulum, a dish of mercury or a pair of spirit-levels are employed to define a truly horizontal surface, and the tilting of the earth's surface relatively to that is observed. This method is practicable only when the displacements of the surface have so great a vertical amplitude, in comparison with their horizontal wavelength, that the slope of the wave is sensible; and, further, only when the changes of slope occur slowly enough to put the inertia of the pendulum or fluid out of account.

On the other hand, the inertia method is applicable only when the displacements have so short a period, in comparison with their amplitude, that the acceleration of the ground, during

[1] Paper read before Section A of the British Association at Aberdeen, by Prof. J. A. Ewing, of University College, Dundee. (Abstract.)

the greater part of the motion, is large relatively to the frictional resistance of the suspended mass.

Between ordinary earthquakes and tremors, on the one hand, capable of observation by the inertia method, and slow earth-tiltings, on the other, capable of observation by the equilibrium method, it is at least possible that there may be many movements, not reducible to either type. For example, if successive upheaval and subsidence of small amplitude were to occur with a very long horizontal wave-length, and with a period of (say) one or two minutes or more, it would be practically impossible even to detect its existence by either of the methods named, unless by chance it were repeated several times with uniform period in the presence of a very frictionless vibrator whose free period happened to agree nearly with the period of the disturbance; even then, no measurement of its amount could be made. We are in fact forced to classify earth-movements under the two heads which have been named, not because there is any necessary discontinuity between the two, but because they must be treated by two entirely distinct modes of observation.

For the measurement of palpable earthquakes by the inertia method, the writer has devised many instruments which have been successfully applied to the registration of Japanese earthquakes, and which are described in a memoir on earthquake measurement, published in 1883 by the University of Tokio. He has not attempted in any case to give the astatically suspended mass three degrees of freedom, and nothing would be gained by doing so. An instrument with two degrees of freedom is now exhibited to the Association. It consists of an ordinary pendulum coupled with an inverted pendulum, in such a manner that the two bobs move together in any horizontal direction. This combination of a stable with an unstable mass can be adjusted to give any desired degree of astaticism. In practice it is convenient to allow the joint mass to have a free period of from five to ten seconds, the period of ordinary earthquake waves being much less than this. A long and light lever, pivoted to the frame of the instrument at one point, and to the steady mass at another, forms a registering index, by which a magnified trace of the earth's horizontal movement is deposited on a fixed plate of smoked glass with the least possible friction.

In another instrument two components of horizontal motion are separately determined, each by a horizontal pendulum, tilted slightly forwards to give a small degree of stability, and furnished with a multiplying pointer. In this instrument the pointers trace the successive movements of the earth on a plate of smoked glass which is kept revolving uniformly by clockwork. The velocity and acceleration of the movements are deducible from the records. This is the standard form of seismograph employed by the writer, and, to make the information it gives complete, another instrument for registering (on the same plate) the vertical motion of the ground is added.

The vertical-motion seismograph is a horizontal lever, supported on a horizontal fixed axis, and carrying at one end a heavy mass. A spring attached to a fixed point above holds up the lever by pulling on a point near the fulcrum. To make the mass nearly astatic the point at which the spring's pull is applied is situated below the horizontal line of the lever, so that when the spring, by (say) being lengthened, pulls with more force, the point of application moves nearer the fulcrum, and the moment of the pull remains very nearly equal to the moment of the weight.

Apart from its application to palpable earthquakes the inertia method is to be applied to minute earth-tremors of the kind observed in Italy by Bertelli and Rossi, which are probably to be found wherever, and whenever, one searches for them with sufficient care. But in dealing with them no mechanical means of recording can well be applied, on account of its friction, and a still more frictionless method of suspending the heavy mass is desirable. The writer prefers for this purpose a mode of suspension based on Tchebicheff's approximate straight-line motion; and to detect the movement of the ground he observes, by a microscope fixed rigidly to the frame of the machine, the displacement of the frame with respect to the suspended mass. This is Bertelli's method, except for the substitution of a nearly astatic mass for the stable mass used by him—namely, the bob of a short pendulum—which of course gives a misleading magnification of certain vibrations.

The writer was recently requested by the Directors of the Ben Nevis Observatory to design seismometers for use there, and obtained a Government grant for their construction. The equipment at Ben Nevis will include recording-seismographs, and a micro-seismometer of the kind just described. To measure slow earth-tiltings an instrument is being constructed in which a modification (due to Wolf) of d'Abbadie's arrangement (described in Prof. Darwin's Reports) is followed. Light from a lamp travels some twenty feet horizontally to a mirror inclined at 45° to the horizon. It passes vertically down through a lens which brings the rays into parallelism. They then strike two reflecting surfaces—one the surface of a basin of mercury, the other a plane mirror very rigidly fixed to the rock. The rays come back to form two images near the source, and any relative displacement of the two images is measured by a micrometer-microscope. In the choice and design of this instrument the writer has to acknowledge much assistance from Prof. G. H. Darwin. This apparatus, like the others, was intended for Ben Nevis, but a visit to the Observatory there has convinced the writer that to use it on that site, and in the atmosphere which prevails on the top, would be a matter of extreme difficulty, and that, in the first instance at least, observations should be made with it on lower ground.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Prof. P. G. Tait has been elected an Honorary Fellow of Peterhouse; and Mr. T. T. Jeffery, M.A., a Fellow of the same College.

Mr. J. Larmor, M.A., of St. John's College, has been appointed one of the University Lecturers in Mathematics, and also Examiner for the First Part of the Mathematical Tripos of 1886.

The Syndicate appointed to re-arrange the additional subjects of the Previous Examination have reported in favour of adding Elementary Dynamics to Statics, and reducing the Trigonometry to what is needed for the Examination in Mechanics; Mathematical Honour students, they recommend, shall no longer be required to pass this Examination, but instead be required to pass in either French or German. Physical Science and Biology are still to receive no recognition even as optional subjects.

Dr. Burghardt, Lecturer in Mineralogy in Owens College, Manchester, is appointed to examine in Mineralogy in the Natural Sciences Tripos; Prof. Ray Lankester, F.R.S., to examine in Zoology and Comparative Anatomy in the same Tripos, the First M.B., and the Special Examinations.

Christ's College offers Scholarships and Exhibitions for Natural Science, the Examination beginning January 5, 1886. The Examinations at Jesus College begin on the same day.

The Special Boards for Physics and Chemistry and for Biology and Geology have issued the following notice with regard to the First Part of the Natural Sciences Tripos:—

In Part I. of the Examination all the questions will be of a comparatively elementary character, and will be such as to test a knowledge of principles rather than of details. Specimens may be exhibited for description and determination.

In Physics the questions will be limited to the elementary and fundamental parts of the subject, and, in particular, special attention will be paid to the definition of physical quantities, the general principles of measurement, the configuration and motion of a material system, the laws of motion, the comparison of forces and of masses, and the properties of bodies. In Sound, Light, Heat, Electricity and Magnetism, only the fundamental laws, their simpler applications, and the experiments which illustrate them, will be required.

In Chemistry the questions will relate to the leading principles and experimental laws of Chemistry, the properties of the commoner elements and their principal compounds, the outlines of Metallurgy, and simple qualitative and quantitative analysis.

In Mineralogy the questions will be confined to elementary Crystallography, the general properties of minerals and the special characters of those species only which are of common occurrence or of well-known mineralogical importance.

In Geology the questions will be limited to Physical Geography, the interpretation of the structure of the crust of the earth and the history of its formation, so far as to involve only the elementary parts of Palæontology and Petrography.

In Botany the questions will relate to the elementary parts of Vegetable Morphology, Histology, and Physiology; and to the principles of a natural system of classification as illustrated by the more important British natural orders. Candidates will be required to describe plants in technical language. Questions will not be set on Vegetable Palæontology or the Geographical Distribution of Plants.

In Zoology and Comparative Anatomy minor details will not be included in the questions relating to classification. Geographical distribution of animals is held to be a part of Zoology, and Comparative Anatomy includes the structure of extinct as well as of recent forms.

Human Anatomy will include the mechanism of the human body, the comparison of its parts with those of lower animals, its development, &c.; but the questions will be of a simple and elementary character.

In Physiology the questions will be of a comparatively elementary character.

A practical examination will be held in each of the above subjects.

SCIENTIFIC SERIALS

Verhandlungen der Schweizerischen Naturforschenden Gesellschaft in Zürich, August 7-9, 1883.—We note here the opening address by Prof. Cramer, on unicellular fungi.

Verhandlungen der Naturhistorischen Vereines der preussischen Rheinlande, Westfalens, und der Reg-Bezirks Osndrück, 42nd year, first half, 1885.—The greensand of Aacken and its molluscan fauna, by J. Böhm.—The forest vegetation of the outer North-western Himalaya, by D. Brandis.—On Devonian Aviculaceæ, by O. Follmann.—The biology of water plants, by H. Schenck.

Nouveaux Mémoires de la Société Helvetique des Sciences Naturelles, vol. xxix. part 1, 1884.—Geological sections of the Tunnels of Doubs, by M. Mathay.—On the nisal flora of Switzerland, by M. Heer. Fossil woods from Greenland, by M. Beust.

SOCIETIES AND ACADEMIES

London

Mathematical Society, November 12.—J. W. L. Glaisher, F.R.S., President, in the chair.—Mr. L. J. Rogers, Balliol College, Oxford, was elected a member.—The following gentlemen were elected to form the Council for the ensuing Session:—President: J. W. L. Glaisher, F.R.S.; Vice-Presidents: Dr. O. M. Henrici, F.R.S., Prof. Sylvester, F.R.S., J. J. Walker, F.R.S.; Treasurer: A. B. Kempe, F.R.S.; Secretaries: M. Jenkins, R. Tucker; other Members of the Council: Prof. Cayley, F.R.S., Sir J. Cockle, Knt., F.R.S., E. B. Elliott, A. G. Greenhill, J. Hammond, H. Hart, C. Leudesdorf, Capt. P. A. Macmahon, R.A., Samuel Roberts, F.R.S.—The following communications were made:—On waves propagated along the plane surface of an elastic solid, by Lord Rayleigh, F.R.S.—On the application of Clifford's graphs to ordinary binary quantics, by A. B. Kempe, F.R.S. (Messrs. Hammond and Macmahon put questions to the author).—On Clifford's theory of graphs, by A. Buchheim.—On unicursal curves, by R. A. Roberts.—On some consequences of the transformation formula $y = \sin(L + A + B + C + . -)$, by J. Griffiths.

Linnean Society, November 5.—Sir John Lubbock, Bart., President, in the chair.—Mr. T. Christy exhibited orchids of the genus *Catasetum*, showing that owing to the plants having been moved, the flower in both instances had become malformed.—Mr. E. A. Heath showed a golden eagle in its characteristic plumage of the second year.—Mr. J. Carter exhibited a collection of seeds, lately introduced, remarkable for their peculiarities as specimens under the microscope.—There was shown for the Baron von Mueller a collection of skeleton leaves of species of *Eucalyptus*, prepared by Mrs. Lewellin of Melbourne. These confirm Baron von Mueller's observations as to definite layers, and the relation of these to the skeletonising process. The leaves in decaying produce no bad odour. Von Mueller's observations do not support M. Rivière's statement that the bamboo is as good as eucalypts to subdue malaria; the former dry up, but do not exhale volatile oil as do the latter, and the eucalypts moreover absorb moisture as quickly as Willows, Poplars, and Bamboos.—Dr. Ondaatje showed examples of walking-sticks from Ceylon palms, viz. the Kittool Palm (*Cayota urens*), the Areca and Cocoa-nut.—Mr. J. G. Baker made remarks on an exhibition by Mr. Thiselton Dyer of Darwin's potato (*Solanum maglia*), grown at Kew, the weight of twelve tubers being 28 oz.; also the "papa de Oso," Bear's potato (*S. tuberosum*, var.), grown out of doors from tubers received from Dr. Ernst of Caracas, who obtained them from Merida, where they are found wild.—Then followed a paper, viz. contributions to the flora of the Peruvian Andes, with remarks on the history and origin of the Andean flora, by Mr. John Ball. In this paper the author says that his statements chiefly refer to the western slope of the Cordilleras. From the collections made and other data, so far, therefore, a this region of Peru is concerned, it may confidently be averre that the limit of Alpine vegetation has been placed by previous writers on the subject far too low. In the present instance there can be no serious error as to heights, seeing these are based on those of the railway engineers. The explanation of this relatively high extension of the temperate flora depends on the peculiar climatical conditions. Rain occurs but sparingly, the nights are cold, but frost scarcely known; whereas in the plateau region eastward storms, heavy snow, and frosts are frequent. The vegetation of the region visited Mr. Ball divides into a sub-tropical dry zone from coast to 8000 feet, a temperate zone reaching to 12,500 feet, and an Alpine zone upwards to 17,000 feet, above the sea-level. As regards the proportion in which the natural families of plants are represented in the Andean flora, the Compositæ amount to nearly one-fourth of the whole species, the grasses equal one-eighth, the Scrophularineæ supply five per cent., while Cruciferæ, Caryophylleæ, and Leguminosæ each are represented by about one-thirtieth of the whole. The Cyperaceæ are conspicuous by their absence; a remarkable feature is the presence of four Crassulaceæ. If we take the proportions of the endemic genera and species as criteria, then, as far as materials admit, the Andean flora appears to be one of the most distinct existing in the world. Mr. Ball agrees with those who think it probable that the south polar lands constitute a great archipelago of islands. To this region in question he is inclined to refer the origin of the Antarctic types of the South American flora.—The first part of an exhaustive monograph on recent Brachiopoda, by the late Dr. Thos. Davidson, was read by the Secretary. In this part of his contribution the author reviews the labours of his predecessors in the field, with regard to the shell, to the anatomy of the adult, and to the embryology. As regards the perplexing question of affinities he remarks:—"Now, although I do not admit the Brachiopoda to be worms, they may, as well as the Mollusca and some other groups of invertebrates, have originally diverged from an ancestral vermiform stem, such as the remarkable worm-like mollusk *Neomenia* would denote." He lays stress on the brachiopodous individual being the product of a single ovum, and not giving rise to others by gemmation. He considers that the shell, the pallial lobes, the intestine, the nerves, and the atrial system, afford characters amply sufficient to define the class. The greatest depth at which a living species has been found alive has been 2990 fathoms. As to classification, he groups the recent species into two great divisions:—(1) Anthropomata (Owen) = Clistenterata (King), (2) Lypomata (Owen) = Tretenterata (King). The Anthropomata he groups in 3 families:—1st Fam. Terebratulaceæ, with 7 sub-families and 13 genera and sub-genera, 70 species, and 21 uncertain species. 2nd Fam. Thecideidæ, with 1 genus and 2 species. 3rd Fam. Rhynchonellidæ, 1 genus, 1 sub-genus, and 8 species. The Lypomata he also groups into 3 families, 5 genera and sub-genera, 23 species, and 7 uncertain species:—1st Fam. Craniidæ, with 1 genus and 4 species. 2nd Fam. Discinidæ, with 1 genus, 1 sub-genus, and 8 species. 3rd Fam. Lingulidæ, with 1 genus and 1 sub-genus, and 11 species. He does not concur with M. Delongchamps' scheme (1884) of classifying the Terebratulina, bringing forward Mr. Dall's observations on *Waldheimia floridana*, of delicate spiculæ in the floor of the great sinuses as telling evidence against the arrangement. Dr. Davidson then proceeds to treat of the various genera and species, adding remarks in detail on the Terebratulaceæ from his standpoint, and throughout gives copious descriptions and observations on each.

Royal Microscopical Society, October 14.—The Rev. Dr. Dallinger, F.R.S., President, in the chair.—Mr. Crisp exhibited D'Arsonval's water microscope, a suggestion for improving the means of focusing. The body-tube of this extraordinary instrument contained a glass cylinder which was connected by an india-rubber tube with a syringe. On turning the handle of the syringe water was forced into the cylinder, and the focus was altered according as more or less water was pumped in. Of course, an alteration of focus did result from the operation, but the arrangement destroyed the correction of the objective, and was otherwise objectionable.—Mr. J. Mayall, jun., described Riddell's binocular microscope, which was exhibited by Mr. Crisp, and was of considerable interest, as having been the first binocular microscope with a single objective. He pointed out as a noteworthy feature that it was provided with a means of separating the prisms, so as to give to each eye-piece a full field of view. There was also a screw with a right- and left-handed thread for separating the tubes to suit the width between the observer's eyes. An ingenious application of reflectors at the top of the eye-pieces effected a perfect inversion of the image, so that the instrument could be used for dissecting purposes. It was also a point of special interest in the history of the development of the binocular microscope, that so early as this Prof. Riddell had applied two mirrors for the purpose of equalising the illumination in both fields.—Mr. Crisp exhibited a "twin" simple microscope having two lenses of different powers, also two forms of magnifiers sent by Mr. Hippisley as examples of the capabilities of lenses made out of spherules of glass, and of a simple method of holding them.—Dr. Maddox read his paper, further experiments on feeding insects with the curved or "comma" bacillus.—Mr. Crisp said they had received six slides of material taken from the intestines of Lieut. Kisslingbury, U.S.N., one of the victims of the unfortunate Greeley Arctic Expedition. When the question of cannibalism was being discussed, his body was exhumed, and a good deal of the flesh was found to have been cut off the bones. In order to ascertain if possible what was the last food of which the deceased had partaken, and to establish whether the officers had joined in the cannibalism of the men, the contents of the stomach were submitted for examination. The letter of Mr. C. E. Alling, accompanying the slides (which were sent by Dr. Mandeville and himself) was read to the meeting. Mr. Groves said that although it might be possible to say, from an examination of these slides, whether the material consisted of the flesh of a mammal, a bird, or a fish, it would be quite impossible to say if it was human flesh or not, unless it happened that some hair had been taken with it. Mr. Crisp said that this opinion was confirmed by Prof. Stewart of the Royal College of Surgeons, who, however, thought that a means of identification might be found in the small hairs of the general surface of the body. The slides, however, showed no such hairs.—Mr. P. D. Penhallow's note as to a handle for cover-glasses was read.—Mr. C. Beck exhibited a compact form of Mr. Stephenson's catadioptric illuminator.—Mr. Kitton's and Mr. Kain's notes on balsam of Tolu were read, and Mr. Kitton's note on a new diatom, *Navicula Durrandii*.—Mr. J. C. Stodder's note was read, giving the views held by the late R. B. Tolles on the formation of a small battery of objectives to cover reasonably well all the requirements of the general microscopist: 3 in., 1 in. (30°), 4-10 in. (110° dry), 1-10 in. (oil-glycerin-water immersion with a balsam angle of not much less than 120° for best results).—Mr. C. D. Ahrens' paper on an improved form of Stephenson's erecting and binocular prisms was read, in which he proposed to unite the lower prisms by a wedge of glass. He also proposed an alteration in the upper prisms (when they are used in place of a plate of glass).—Mr. T. B. Rosseter's paper on the uses and construction of the gizzard of the larva of *Corethra plumicornis* was read by Prof. Bell, and prepared specimens in illustration exhibited.—Mr. Dowdeswell's paper on the cholera comma-bacillus was read.—The President called the attention of the meeting to the death of Mr. Robin, the eminent histologist, and one of the Honorary Fellows of the Society.—Seventeen new Fellows were elected and proposed.

Paris

Academy of Sciences, November 9.—M. Jurien de la Gravière in the chair.—Determination of the mechanical work effected in human locomotion (one illustration), by MM. Marey and Demeny. This is an attempt to estimate the quantity of muscular energy developed by man in the various forms of locomotion from the physiological standpoint, which is shown to be different from the mechanical. Three chief elements in the measurement of muscular action in horizontal movement are here considered separately: The labour expended along the vertical; the labour expended along the horizontal; and the labour required for the oscillation of the lower member during its suspension.—Variations in the mechanical labour expended in the different attitudes of man during locomotion (three illustrations), by the same authors. The estimates here recorded are the results of experiments made on two persons only, walking and running on the level. The experiments will require to be repeated on a large number of subjects in order to determine the influence of weight, height, slope of the ground, and thus arrive at a mean average.—On the radicular nature of the stolons of Nephrolepis: a reply to M. P. Lachmann, by M. A. Trécul.—On the derivation of the solutions in the theory of the Cremona transformations, by M. de Jonquières.—Note on the combe of Péguère, near the thermal station of Cauterets, Pyrenees, by M. Demontzey. The destructive landslips to which this upland valley has long been subject, are shown to be due to denudation and erosive action, hence may be prevented by gradually restoring the vegetation along the steep slopes of the surrounding mountains.—Experimental researches tending to show that the muscles affected by *rigor mortis* remain endowed with vitality till the appearance of putrefaction, by M. Brown-Séquard. Experiments made on dogs some days after being killed seem to render it probable that muscular rigidity is not a state of absolute death, but a transition from life to death, a transition which may last for weeks.—On the action of a mixture of sulphate of copper and lime on the mildew of the vine, by MM. Millardet and U. Gayon.—Analytical theory of the movements of Jupiter's satellites, second part: Reduction of the formulas to numbers, by M. C. Souillart.—An undated letter of the Countess de Lafayette (reign of Louis XIV.) addressed to Segrais, and inviting him to witness "the experiment with an artificial fire giving warmth the whole day for two sous," by M. Feuillet de Couches.—Application of M. Lœwy's new methods for the determination of the absolute co-ordinates of the circumpolar stars without the necessity of ascertaining the instrumental constants (right ascensions), by M. Henri Renan.—On the numerical tables intended to facilitate the transformations of co-ordinates in astronomical calculations, by M. Vinot.—On the irregular integrals of linear equations, by M. H. Poincaré.—Note on the compressibility of fluids, by M. E. Sarrau. The formula—

$$p = \frac{R\,T}{v - a} - \frac{K}{T(v + \beta)^2}$$

proposed by M. Clausius for carbonic acid, in which p = the pressure, v = volume, and T = absolute temperature, is shown to be applicable to other gases. The author claims that for these gases he had deduced the elements approaching the critical point before the experiments of MM. Wroblewski and Olszewski.—On two new kinds of radiophones, by M. E. Mercadier. With these instruments, which he names the "thermo-electrophone" and the "thermo-magnetophone," the author thinks it will be possible, with an intense solar radiation, to reproduce articulate speech.—An explanation of the anomalous magnetic effects produced by the discharges of condensers, by M. Ch. Claverie.—Note on Schlœsing's law respecting the solubility of the carbonate of lime by carbonic acid, by M. R. Engel.—On a coloured reaction of rhodium, by M. Eugène Demarçay. Certain blue solutions of rhodium yield with potassa a greenish precipitate, which changes to a dark blue in acetic acid. This colouration appears due to the formation of a salt corresponding to the green hydrate of bioxide of rhodium.—On the antiseptic and other properties of rosolene (retinol, $C_{32}H_{16}$), by M. Emile Serraut.—On the root of *Danais fragrans*, Comm. (yellow liane) and its chemical composition, by MM. Edouard Heckel and Fr. Schlagdenhauffen.—On the composition and fermentation of interverted sugar, by M. Em. Bourquelot.—On the hypnotic properties of phenylmethylacetone (acetophenone), by MM. Dujardin-Beaumetz and G. Bardet.—On the nervous system of Phylloxera, by M. Victor Lemoine.—On the Limaciæ of the neighbourhood of Saint-Vaast la Hougue, department of La Manche, by M. S. Jourdain.—Variations in the respiration of plants at the different stages of development, by MM. G. Bonnier and L. Mangin.—On a rare amygdaloid granite from the Riaillé Quarry, Saint-Hilaire de Loulay, Vendée, by M. Stanislas Meunier.—On some fragments of human skulls and a potsherd found in immediate association with two skeletons of *Ursus spelæus* in the Nabrigas Cave, Lozère, on August 28, 1885, by MM. E. A. Martel and L. de Launay. The discovery of these remains seems to place beyond doubt the existence of man already possessing a knowledge of the potter's art at the epoch of the Cave bear in the Lozère district.—On the relation of whirlwinds and waterspouts to cyclones, by M. Ad. Nicolas.—Remarks on M. Jourdy's "Geology of East Tonkin," by M. Albert Gaudry.

BERLIN

Meteorological Society, October 13.—The President, Geheimrath Dr. Thiel, reported that, in accordance with a resolution passed by the Society in furtherance of the establishment of a thickly planted series of rain-stations, rain-gauges had been set up at seven places in the outskirts of Berlin to the north-west and west, and since July had been working well. It was to be hoped that their number would soon be increased and that a lengthened series of observations would yield data for an exact determination of how closely rain-gauges must be placed to each other, in order to obtain a correct representation of the rainfall of any district.—Dr. Hellmann then, after a brief historic survey of the institution of meteorological stations at high points, gave a full description of the meteorological observatory at Ben Nevis in Scotland, which he had visited in August last. The topographical situation of the station, the construction and position of the instruments, and the mode of observation were set forth, while some of the climatic peculiarities of this station, such as its great humidity, its small yearly and daily variations of temperature, its scanty sunshine, the frequent reversal of the change of temperature with the height, and other particulars, were also remarked on. Following up the minute description of this important high station in Scotland Dr. Hellmann enumerated all the stations on the peaks of mountains that had hitherto been erected, which comprised only the Puy de Dôme and Pic du Midi in France, the Säntis in Switzerland, the Schafberg and Hochobir in Austria, the Schneekoppe and Brocken in Prussia, and Mount Washington and Pike's Peak in the United States of America. Of these stations only the two French, the Swiss, and the Austrian were of the first rank, or between the first and second rank. In addition to these stations on mountain tops there was a whole series of high situated meteorological stations on mountain passes and plateaus in operation, which collected valuable material towards the meteorology of the higher atmospheric strata, in Italy, Switzerland, Germany, India, South America. In the case even of a temporary residence at high situated points brief but very valuable series of observations had been gained—at Ararat, for example. It must, nevertheless, be the endeavour of scientific meteorology to increase the number of mountain-top stations of the first rank, and the speaker expressed the hope that under the contemplated reorganisation of the meteorological service in Germany, and particularly in Prussia, at least one mountain-top station of the first rank, namely, on the Schneekoppe, which was very peculiarly adapted for this purpose, would be established. In the discussion which followed it was maintained on one hand that self-registering instruments at high stations were perfectly useless, and on the other hand that even tourists, many of whom every summer reached heights beyond 4000 metres high, might, by means of portable pocket instruments, supply contributions quite available towards the meteorology of the higher strata. A member of the Society gave some proofs to this effect, and mentioned the remarkable fact that the red-brown ring round the sun, which he had everywhere seen distinctly, appeared from Monte Rosa, not red-brown, but very distinctly reddish-yellow.—Dr. Börsch related that during a determination of longitude between Berlin, Breslau, and Königsberg, the observer in Berlin on August 2 was sensible of such lively disturbances of his level that he was obliged to discontinue for a time the use of the transit instrument, and considered the oscillations to be seismic. When he afterwards read in the newspapers of violent earthquakes in the interior of Asia having happened at the same time, he made inquiry of the observers at Breslau and Königsberg, and learnt that they too had been disturbed by lively oscillations of the ground. These vibrations had been all the stronger the more to the east was the station, a circumstance which likewise pointed to a connection with the earthquakes of the interior of Asia. More careful observation of such phenomena would render possible the exact measurement of the propagation of earth-vibrations.

THURSDAY, NOVEMBER 26, 1885

THE WHOLE DUTY OF A CHEMIST

ON the 6th instant there was a meeting at the rooms of the Chemical Society in the afternoon, and a dinner in the evening, to celebrate the grant of a Royal Charter to an Institute of Chemistry.

The stated object of the Institute is to do for chemists what has been done for the members of different professions and trades by such bodies as the College of Physicians, the College of Surgeons, the old Guilds, and the modern Trades Unions.

This is possibly a very desirable thing to do, but to the student of pure science the creation of the new corporation possesses no other interest than that which results from the consideration of its prospective influence on the progress of science. Indeed the intention is so entirely commercial that we should not have referred to the new body at any length in these columns if the President, Prof. Odling, in an address delivered on the occasion, had not enunciated views which we believe all true men of science will read with pain, and against which we feel it our bounden duty to make a protest.

Before we proceed to deal with the address itself, it will be well to clear the ground by a few general considerations touching the applications of science to industry, and the manner in which, time out of mind, and we hope for all future time, scientific principles have been and will be brought down to be utilised in the ordinary affairs of life. First of all, it will be readily conceded that in the present state of civilisation there is scarcely any handicraft or manufacture or process in which some scientific fact or principle does not lie at the root of the matter. Our boots are the results of scientific applications, our clothes are the result of scientific applications, the materials depend upon science, the fit depends upon science. If one had to define offhand the difference between a profession and a trade requiring skill in making certain articles, one would say that the profession required more science than the trade, that is, there is not a difference of quality, but of quantity. The bootmaker that makes a boot, and the surgeon that cuts off a toe, both deal, if they do their work well, with the anatomy of the foot, but we expect the professional surgeon to know more about this anatomy than the shoemaker. Further, any science in the process of the amalgamation of its applications with other similar amalgamations at first begins by being in the hands of a few individuals, let us say of high training; it becomes generalised, and then finds itself in the hands of a greater number of individuals probably less highly trained, and so on, till each special application of science becomes the common property of the community.

Au fond, then, so far as science is concerned, we can recognise no distinction between a profession and a trade, or we may use the words an industry, if any one likes them better. These industries or professions once started are kept alive and fostered, and made more useful for mankind, by the perpetual introduction of new scientific facts and processes. This is as true for the improvement in leather and cloth manufactures, as it is in the curing of hydrophobia, which may some day come.

Chemical science, for example, is the very sap of the chemical industries, and there is the most intimate and the most direct connection between the researcher and the manufacturer. A Reichenbach discovers paraffin, and a Young straightway turns it into candles. Andrews demonstrates the true principles of the condensation of gases, and these principles are forthwith applied to the construction of a freezing-machine. The history of technology teems with instances of this kind. Indeed, some of the huge manufacturing concerns of the Continent are driven to anticipate the output of the purely scientific laboratories of the Universities and higher schools by employing investigators for themselves: the great colour-making manufactory at Ludwigshafen has two score of chemists at work on the industrial development of the chemistry of aromatic compounds. Now these investigators are in the first instance made by the Universities; they are the product of their great chemical schools—they are men who have caught something of the spirit of that noble army of teachers who have dedicated their lives to the advancement of natural knowledge for its own sake without thought of guineas or "leading professional position." The growth, then, of the chemical trades must depend ultimately on the help which chemists are able to give to the chemical traders. This help must consist either in new knowledge to be furnished directly by the chemist, or indirectly by the men whom he has so trained that they may know how to seek for it and to find it. Have we not here the true function and real duty of "those of us occupying the leading position in the profession" or "who have already attained the higher steps of the ladder of success," if such men are connected with an University?

The honour given to teachers from the beginning of time was accorded to them not merely for their learning but for the new knowledge they produced and taught. They were the guardians of the sacred fire; and the reverence with which they were regarded depended upon the constancy with which they fed the flame. The estimation in which men of science are held to-day, even if they are not teachers, is due to the national benefits which they confer by giving their lives to learning, teaching, and to writing books for others; and because such men are regarded as the highest benefactors of our race and the founders of our modern civilisation. The nation remembers them even if they often forget themselves.

Such men, however, do not exhaust the number of those who have studied science or who perform useful scientific functions. But the point is, however useful this other class of men may be—like the bootmaker and the tailor, who are eminently useful in their way—their knowledge is merely a stock-in-trade to which they look for their livelihood. We have nothing whatever to say against these men, but it is imperative that we should point out that if their object in life is merely to get money the public estimation of them cannot be expected to be the same as that accorded to those whose lives are devoted to the public good. Is it possible to tell one kind of man from the other?

This can be easily done. Let us assume that he is a professor of science at a well-known seat of learning. Are his lectures the best possible, or does he simply lose the time of his students for so many hours per term?

Is he the life of his laboratory, always there, always setting an example to his students of patient and continuous research? What is the number of researches produced per annum, and what is their value? Do his students revere him or think little of him? Do they give any indications of benefiting by his instruction? Has he founded a school? Has he impregnated his assistants with the love of new knowledge, and do they spend their time in getting it? Or, again, is he the friend of manufacturers, a *grata persona* to limited liability companies? Is he a noted expert in our courts of law? Is he never seen in his laboratory? Is the laboratory now silent, its appliances rotting from disuse, and its old reputation for research become merely the shadow of a shade?

It is really quite easy to find out whether this professor of science is doing his duty or neglecting it; whether the getting of knowledge or the getting of money is foremost in his thoughts.

The dignity of a professor in a seat of learning is closely associated with the dignity and the honour of the seat of learning itself. An University which appoints a man to a professorship places its honour in his keeping so far as his science is concerned. Now the members of an University, even though they may not be especially learned in any particular branch of knowledge, soon know, perhaps even by a kind of instinct, whether a professor is upholding the honour of the *alma mater*, in the welfare of which they are all interested; or whether by forsaking the fair fields of knowledge, and by thinking only of self and pelf, he is dragging her reputation through the mire. This feeling in an University affords another criterion which may be safely relied on if we wish to know whether or not a professor is doing his duty.

Take another case. Let it be that of one who is engaged in commercial matters—whether large or small is immaterial to our argument—into which scientific principles and ideas largely enter; or let us assume him to be engaged, on the strength of his scientific attainments, by a Government department or an industrial body which wishes to utilise his knowledge. Does he expand his routine work into an opportunity of enriching science? Does he make himself the recognised master of a large field of knowledge which he gives to the world? Do his labours confer honour on himself or on the body with which he is connected? Or, on the other hand, is his name never heard at a scientific society? does he merely, in short, content himself with the perfunctory performance of the work by which he makes his money?

We have referred to the dignity of a man of science; what does this mean? The view it expresses is simply the modern view representing that feeling of olden time which made teaching so honourable while trade was despised. Then, as now, the man was often poor, but he spent his life in doing a common good, while the trader was often rich, and dispensed his wares for his own advantage. Nowadays the dignity of a leading man of science is somewhat difficult to define exactly, but the same idea lies at the bottom of it. It is known that he cares more for science than for money. It is known that his whole heart is in his researches; even when they happen to be profitable to himself or to others, he is still not a money-grubber. This dignity is not confined to professors, but a man to possess it must be something more than commercial or professional. We cannot imagine a bootmaker or a tailor on the council of the Royal Society, but yet he employs scientific processes to get his money as much as a chemist does who spends his time in commercial analyses or in courts of law. To come back to our criterion, we think we have indicated that there are various ways in which men of science can be allocated in the two classes to which we have referred.

We now proceed to refer specially, and as briefly as we can, to Prof. Odling's address. It begins with a history of the movement, and then goes on to show the ever-increasing need there is of "professional services" which are rendered by men of various grades, "from those of us occupying the leading positions in the profession, to the most humble individual practising in our ranks." We are dealing, then, with the chemists employed by Government and large corporations, as well as "experts" and analysts; and among these latter not only with the man of "leading position" who charges ten guineas for analysing a sample of water, but with the assistant who actually does the work for the not excessive sum of half-a-crown.

We next read as follows:—

"It would seem, however, from observations not unfrequently hazarded by some very superior persons, whose happy mission it is to put the rest of the world to rights, that there is something derogatory to the man of science in making his science subservient in any way to the requirements of his fellows, and thereby contributory to his own means for the support of himself and of those depending upon him. Now, on this not uncommon cant of the day a little plain speaking would seem to be very much wanted. While the investigation of nature and the interpretation of natural law are admittedly among the highest, as they are among the most delightful, of human occupations, the right application of natural law to effect desirable objects is in itself a scarcely less worthy occupation; many of these objects being of paramount importance, and attainable only by the exercise of high scientific sagacity and skill, aided by a fertility of resource and a persistent elasticity of spirit, ready ever to cope with the successive novel difficulties found to be continually opposing themselves."

On this we have to say—and we shall return to the point further on—that we know of no one who has made the abstract proposition which Prof. Odling condemns. We are prepared to say, however, that in the opinion of many who are not men of science, the appearance of a man of science, occupying a "leading position" as an expert in a court of law, whose "devotion" to his employer causes him to apparently contradict the statements of another man of science on the other side, doubtless equally "devoted," does not add to his dignity. A well-known lawyer, now a judge, once grouped witnesses into three classes; simple liars, damned liars, and experts. He did not mean that the expert uttered things which he knew to be untrue, but that by the emphasis which he laid on certain statements, and by what has been defined as a highly cultivated faculty of evasion, the effect was actually worse than if he had.

It is consoling to think that the qualities most valuable in an expert, since experts there must be, are not those for which men of science are best known. Coolness under cross-examination, verbal dexterity, a ready wit, not too much knowledge or conscience, the fidelity of a partisan, or rather "*professional devotion*," and a dash of impudence, are quite as frequently the passport to the "professional eminence" of an expert as scientific ability.

Surely it is not necessary for us to point out the sophistry and fallacy of the argument that "the right application of natural law to effect desirable objects is in itself a scarcely less worthy occupation" than "the investigation of Nature and the interpretation of natural law," when such applications are made at the instigation of an individual—a client—who pays for such application of natural law at the rate of so many guineas a folio; and who, if it suits him, may then proceed incontinently to suppress "the right application of natural law." Are we to elevate such service as this to a high moral platform, and claim for it the same homage or appreciation which is accorded by the outside world to work done unselfishly and for the benefit of the whole community?

Prof. Odling strengthens his view that we should by the following considerations:—

"In this matter, as in so many others, the sense of proportion is but too often lost sight of. Because the investigations of a Newton, a Darwin, a Dalton, a Joule, and a Faraday have an importance of which few among us can adequately conceive even the measurement; because among the scientific men now or but lately living in our midst are to be found those whose investigations in pure science have not only won for them a high renown, but have earned for them the gratitude, and should have obtained for them the substantial acknowledgments, of their country and the world; and because even the minor investigations and discoveries, placed before the world for the world's use, and not merely to enrich a firm, that are ever being made in pure science have all of them their merit and their value, it does not follow that the mere accomplishment, it may be in an abundant leisure, of two or three minor investigations, however creditably conducted, are to lift their authors into a scientific position altogether above that of men whose laborious lives have been spent in rendering their great scientific attainments directly serviceable to the needs of the State and of the community. The accomplishment of such-like investigations does not entitle their authors to claim exemption from the duty of earning their own livelihoods or give them a claim to be endowed by the contributions of others with the means to jog leisurely along, without responsibilities and without anxieties, the far from thorny paths of their own favourite predilection. However heterodox it may be thought by some, the best of all endowments for research is unquestionably that with which the searcher, relying on his own energies, succeeds in endowing himself. The work to which our natures are repugnant, not less than the work which entrances us and hardly makes itself felt as work at all, has to be done. In some degree or other, we have most of us to obtain our own livelihood; and harsh as may seem the requirement, it will, I suppose, be conceded that the necessity put upon the mass of mankind of having to earn their daily bread is an arrangement of Providence which has on the whole worked fairly well; and, further, that the various arrangements hitherto tried for exempting certain classes of men from the necessity of having to earn their daily bread, in order that they might give themselves up to the higher spiritual or intellectual life, have scarcely, to say the least of them, worked quite so satisfactorily as they were intended to. All of us are, without doubt, qualified for higher things than the mere earning of our daily bread; but the discipline of having to earn our daily bread is, in more ways than one, a very wholesome discipline for the mass of us, and even for the best of us. It may here and there press hardly on particular natures, but it is rarely an impediment to the achievement of the highest things by those having the moral qualities, the judgment, the determination, and the self-denial necessary above everything else for their achievement. Not a few of us may consider ourselves fitted for higher work than the gods provide for us, and fondly imagine what great things we should effect if we could only have our daily bread supplied to us by the exertions and endowments of other less gifted mortals. But experience is not on the whole favourable to the view that, the conditions being provided, the expectation would be realised. Experience, indeed, rather favours the notion that it is primarily the necessity for work, and association with those under a necessity to work,—those in whom a professional spirit has been aroused, and by whom work is held in honour,—that creates and keeps up the taste and the habit of work, whereby the vague ambition to achieve is turned to some productive account. Take, say, a thousand of the most eminent men the world has produced, and making no allowance for the large influence of descent or training, or of association with those to whom work is a necessity, or having been a necessity has become a habit, consider what proportion of these men have, by their means and position in early life, been free from any stimulus or obligation to exert and cultivate their powers; and consider, on the other hand, what proportion of them have been stimulated to exertion and success by the stern necessity of having either to achieve their own careers, or to drop into insignificance, if not indeed into actual or comparative degradation and poverty. We ought, indeed, all of us to be students, and to be above all things students; but the most of us cannot be, nor is it desirable, save in the case of a special few, that we should be only students. We have all our duties to fulfil in this world, and it is not the least of these duties to render ourselves independent of support from others, and able ourselves to afford support to those depending upon us. Fortunate are we in being able to find our means of support in the demand that exists for the applications of a science which has for its cultivators so great a charm. To judge, however, not indeed by their coyness when exposed to the occasional temptation of professional work, but rather by their observations on the career of others, the most sought after and highest in professional repute, the pursuit of professional chemistry is, in the opinion of some among us, a vocation open to the gravest of censure. It is praiseworthy, indeed, for the man of science to contribute to his means of livelihood by the dreary work of conducting examinations in elementary science for all sorts of examining boards, and by teaching elementary science at schools and colleges, and by giving popular expositions of science at public institutions, and by exchanging a minor professorial appointment, affording abundant opportunities for original work, in favour of a more lucrative and exacting appointment involving duties which, if rightly fulfilled, must seriously curtail these same opportunities. It is praiseworthy of him to add to his means by compiling manuals of elementary science, and by writing attractive works on science for the delectation of general readers; but it is, forsooth, derogatory to him, if not indeed a downright prostitution of his science, that he should contribute to his means of livelihood by making his knowledge subservient to the wants of departments, corporations, and individuals, alike of great and small distinction, standing seriously in need of the special scientific services that he is able to render them.

"A glance back suffices to show how foreign to the ideas of the great men who preceded us is this modern notion of any reprehensibility attaching to applied or professional science. In his earlier days, Prof. Faraday was largely employed in connection with all sorts of practical questions, and until almost the close of his life, continued to act as scientific adviser to the Trinity House. No man was more constantly occupied in advising with regard to manufacturing and metallurgic and fiscal questions than Prof. Graham, who ended his days holding the official position of Master of the Mint; a position in which he succeeded another eminent man of science, less known, however, as a chemist than as an astronomer, Sir John Herschel. . . .

"So far, moreover, from his professional eminence and usefulness being made a matter of reproach to the scientific man, it should constitute rightly a claim to his higher consideration; and far from being accounted a disparagement, should be held as an addition to his scientific standing. In the professions most allied to our own on the one side and on the other this is well recognised. The physician and the engineer are not merely students of pathology and of mechanics, however important may have been their contributions to pathology and mechanics respectively, but they are the distinguished craftsmen in their respective arts. And whether or not they may have made important contributions to pure science, their rank as eminent scientific men is everywhere and rightly conceded to them. A lucky chance happening to any professional man may indeed bring him to the front, but no succession of lucky chances can ever happen that will of themselves prove adequate to keeping him there. Great qualities are ever necessary to sustain great professional positions; and to be for years one of the foremost in a scientific profession is of itself at least as substantial an evidence of scientific attainment as is the publication of a memoir on some minute point, say of anatomy, or chemistry, or hydrodynamics, for example. And it is so recognised, and very properly recognised, even in quarters where pure science admittedly reigns supreme. Leading engineers and leading physicians and surgeons are every year admitted into the Royal Society, not on account of the importance attaching to any special contributions they may have made to mechanical or pathological science, but mainly because of their eminence in their several professions, in which to be eminent is of itself an evidence of scientific character and of extensive scientific knowledge. It may indeed be taken as beyond question that to obtain and retain a leading position in a scientific profession, needs among other things the possession of high scientific attainments. I say among other things, for without moral qualities in a notable degree, sympathy, endurance, courage, judgment, and good faith, no such professional success is conceivable. Professional eminence is the expression necessarily of scientific ability, but not of scientific ability alone. The self-engrossing science of the student has to be humanised by its association with the cares and wants, and the disappointments and successes of an outside world."

Having given this long extract from the address, we now proceed to remark on certain parts of it.

In the whole of Prof. Odling's references to the endowment of research, which was so warmly advocated by his predecessor at Oxford, Sir Benjamin Brodie, there is much evidence that he has not even begun to understand the question. No one has ever proposed to endow research for the benefit of the researcher, or to endow researches which are immediately remunerative. The highest needs of the nation and of learning have been alone considered. The idea of endowment was only suggested for the encouragement of such researches as promised no immediate return in the shape of utility, except as pure knowledge. Prof. Odling seems to imagine that if the Fellowships of an University were awarded to men of eminence in science or who had given proof of skill in research, the Fellows would be but charity-boys of larger growth. When Prof. Huxley told the Americans that any country would find it greatly to its profit to spend 100,000 dollars in first finding a Faraday, and then putting him in a position in which he could do the greatest possible amount of work, he was not thinking that Faraday would thus be enabled to give nice dinners, but of the results of that greatest possible amount of work—the new knowledge that would be certain to be garnered and utilised some day for the nation's good. The endowment of research, or aid to research in any form, seems to be so objectionable to the President of the Institute, that the winding up of the Research Fund of the Chemical Society would seem to be one of the most desirable things of the present time, if his opinion is to prevail.

Prof. Odling employs in his argument a well-known method of procedure often used to throw dust in the eyes of a jury. He has put up a bogus case in order to demolish it very much to his own satisfaction. We fear that in this process he has been guilty of much, doubtless unconscious, misrepresentation of many revered names in science. This dummy is the assumed opinion of men of science that a man of science should do nothing to help industry directly. This opinion, as we have before stated, nowhere exists. The opinion does exist, as we have already implied, that such assistance must not interfere with higher work if higher work has been undertaken; and the general consideration of the man of science has risen enormously when it has been known that such aid, when given, has been given openly to all-comers, and not in secret to him who could pay the highest fee. Prof. Odling, in apparent justification of his case, quotes, amongst others, the names of Faraday and Graham, and states roundly that they have done the thing to which the superior persons to whom he refers object. This is untrue; no men were more faithful to their trust than Faraday and Graham, and the proof of our contention lies in the fact that their names are honoured among us while others, their contemporaries, the Ures and Lardners of that day, although men of tremendous "professional eminence," are already forgotten, or live only in the pages of a Thackeray. It has been stated over and over again that such was the fidelity of Faraday to his trust that he refused sums which would have amounted in the aggregate to a large fortune which were offered to him by manufacturers and others to tempt him to neglect his public work for their private advantage. It was a subject of pride to him that he had refused pay for all work he had done for the Government except on one occasion when he accepted it for the sake of a coadjutor. The volumes of Faraday's and of Graham's researches, not to mention those of other honoured names, representing their fidelity to pure investigation during the whole of their working lives, are, after all, the best answers to Prof. Odling, and when we contrast their faithful and long-continued activity in this direction with that of others which began with almost as fair a promise, and then suddenly, before the men were in their prime, was seized by a paralysis or else diverted into other channels, we have an indication, by no means to be despised, of the possible result of merely commercial work.

We believe that some chemists, although they hold the views which we express in this article, have allowed their names to be connected with the new institution, because they think that it may eventually, somehow or other, aid chemical education in this country. We think that this is an error. The College of Physicians has been pointed out as a precedent for the Chemical Institute. Now what has the College of Physicians done for medicine and for medical education? Although it was one of the first founded of the Professional Guilds, we have had repeated occasion to point out in these columns that in the opinion of the most competent authorities, medical education even to-day is the worst organised and least effective.

The latter part of the extract gives Prof. Odling's view as to the easy admission afforded by professional eminence into the Royal Society. As regards engineers, we have never heard of any one being elected into the Royal Society except on the ground of his contributions to science. Commercial or professional eminence has, so far as we know, not been considered. As regards doctors, owing to the ancient ties of the Royal Society with medicine, we believe that it has been the custom to consider, in judging their claims, that marked eminence in their profession should be taken into account; but professional eminence *alone* does not decide the choice. In saying this we do not express our own opinion merely; and we must add that there is no written law in the matter, the decisions each year resting with the Council of that year, and the Council, as is known, is an ever-changing body.

The latter part of Prof. Odling's address, which we have not space to give at length, deals with the advantages which in his opinion are likely to result from the new organisation. He also gives some paragraphs from the preamble of the charter under which the Institute has now been incorporated. One of these paragraphs runs as follows:—"That the said Institute was not established for the purposes of gain, nor do the members thereof derive or seek any pecuniary profits from their membership." We confess we find it difficult to harmonise this extract from the charter with the general drift of the part of the address now under consideration; for although Prof. Odling frankly acknowledges, to quote his words, "to those of us who have already attained the higher steps on the ladder of success it can scarcely afford any personal advantages whatever," it is clear that this is not to obtain universally. Among the "advantages" we find not only "gain to the public" but "gain to ourselves"; we read of "noteworthy advantages, social and material, to the persons" who form the Institute. We also read: "Among its other objects, the Institute of Chemistry exists undoubtedly for the purpose of improving the position and prospects of professional chemists"; we further find that the Institute "will add alike to the social and substantial attractiveness of the chemical profession."

We do not find too many references to researches not of a directly remunerative kind, but Prof. Odling makes one concession: he thinks that among the members of the Institute "some proportion, at any rate, will find the pursuit of research the vocation for which they are especially qualified, and for which they will, IN THE SEED-SOWING TIME OF THEIR LIFE, be willing to make, as others have made before them, even considerable professional sacrifices."

Ilias in nuce. In the phrase we have put into capitals we have the real key to the address. It would appear that the life of a chemist should be divided into two periods—Seed-time and Harvest. Research may be the seed, the harvest must be gold. The continued pursuit of truth, the continued love of science for its own sake, may be left to the unwise. The ideal chemist is one who uses research only as an investment. He carefully limits it to his earliest years. By it he is to gain a reputation as a man of science. His reputation thus gained procures for him a post of high scientific honour and position. The "seed-sowing time" is now over. The golden harvest is ripe. It has to be reaped and garnered. The duties of the position of honour obtained by the original investment are therefore to be thrown to the winds in order that this may be done. He is now a man of "professional eminence": he is now on "the higher steps of the ladder of success."

Does any one think that his electors have a right to protest or his friends to lament? Certainly not; they have no such right. Their feelings have simply arisen from their ignorance of the Whole Duty of a chemical Man.

In these days of rapid intercommunication among nations we know that Prof. Odling's address will be carried to our brethren beyond the seas and to many centres of scientific activity in other lands. We wish it to be known, therefore, that the spirit it breathes is an alien spirit, repugnant to students of pure science in this country.

CENTRAL AMERICAN COLEOPTERA

Biologia Centrali-Americana. Insecta: Coleoptera. Vol. I. Part I. By H. W. Bates. (London: R. H. Porter, 1881-84.)

THIS part of Godman and Salvin's great work is now complete, and though called a part is practically a volume, with introduction, indices, and completed pagination; its publication has extended over four years. It deals with the two great families of carnivorous beetles—the Cicindelidæ and Carabidæ—and consists of 316 pages of letterpress and thirteen plates of coloured figures. The number of species of the two families recorded from the region is 1086, belonging to 154 genera. Nine new genera and about 450 new species are described, this latter figure including, however, a certain number of species characterised for the purposes of this work in the *Proceedings* of the Zoological Society for 1878 and a few others similarly dealt with in the *Annals and Magazine of Natural History.* In his introduction the author touches on some points of geographical distribution, and states that the inclusion of the central highlands of Mexico and Guatemala in the Nearctic province by Wallace is not supported by these insects, but that on the contrary they markedly confirm the essentially Neotropical character of the Central American fauna. He also is inclined to adopt the opinion that the Central American region comprises two distinct sub-provinces, as proposed by Salvin from his study of the birds, the line of division passing probably across Nicaragua; and considers that even the more northern of these sub-provinces is not a southern extension of the Nearctic province, but rather a remarkably distinct sub-province of the Neotropical fauna.

In the body of the work the distribution and extent of each genus is briefly stated, and, so far as known, every locality within the region for each species is recorded; thus, as so large a number of new species are described, it is evident that the volume will be an indispensable necessity to every future student of the Neotropical Adephaga. It contains moreover what is practically a new classification of the family Carabidæ. Its author has long been known and respected as an entomological systematist, for it is now nearly twenty-five years since he inaugurated a rational classification of the Rhopalocera or butterflies. He has been recognised since the death of Baron Chaudoir as the one entomologist possessing an extensive yet intimate knowledge of the Carabidæ of the whole world. But Chaudoir, though he published a crowd of valuable memoirs on the family, died without leaving behind him any general work on its classification. It is therefore a matter for congratulation that the author of this beautiful volume has presented us with a systematic arrangement as complete as the faunistic nature of the work permitted; it is one that requires, indeed, comparatively little supplement from the faunæ of other countries to render it quite complete. Assisted by the labours of Latreille, Dejean, Lacordaire, Schiödte, Leconte, and Chaudoir, and availing himself largely of the valuable work recently published by Horn, he has been able to form of the numerous sub-families, which are the equivalents of Horn's tribes, aggregates of greater importance, which he terms subdivisions. The family Carabidæ is of such enormous extent—12,000 species being known, with a vast number of others to come—that the necessity of some series of intelligible aggregates subordinate to the division, but superior to the tribe or sub-family, is undeniable, and Mr. Bates' attempt to furnish such a series is therefore of great value, even though his subdivisions are at present capable of only loose and partly traditional definition. The division II, of Carabidæ comprises eight of these subdivisions based chiefly on the form and sexual clothing of the male tarsi and on the form of the apices of the elytra. It is evident that the classification of such an enormous complex as the Carabidæ will require for its perfection the combined efforts of many naturalists, and if Mr. Bates's subdivisions are sufficiently natural they will be gradually evoluted and perfected by others, and we may therefore indicate that the first of them, viz. the Diversimani or Pedunculati seems scarcely tenable. The variability of structure of an organ amounts only to a negative, not a positive statement, and is therefore useless for practical purposes; and if we add to this, that other characters now considered in the Carabidæ to be of much importance, such as the number of glabrous joints at the base of the antennæ, are also subject to much variation in the aggregate, it is evident that a change in its composition is inevitable. We would also venture to call in question the propriety of treating the Pseudomorphinæ as merely a sub-family of Truncatipennes. Horn accords them the much higher rank equivalent to the "division" of Bates, and as they are to a considerable extent synthetic between the universally recognised two great divisions of Carabidæ, it is probable that this will, from a systematic point of view, prove nearly correct. Bates, however, only expresses himself with considerable hesitation on this point, and as the group is chiefly Australian, it will devolve on some student of the Australian fauna to work out this question of primary importance to the classification of the Adephaga.

The thirteen plates with which the volume is adorned supply coloured figures of no less than 325 species representing upwards of 100 genera. The figures are lithographs coloured by hand, and though they are, we believe, about the best that can be obtained in this country at present, they are certainly not equal to some of the refined lithographic figures of insects that have in recent years been produced in Austria; they are, however, so good as to enable the species to be recognised from them with certainty, and will therefore be a very welcome boon to entomologists.

Messrs. Godman and Salvin, the editors of the work, are to be congratulated on this satisfactory completion of the first part of the Coleoptera. No faunistic work that has hitherto been published gives anything near to so complete an idea of the vast wealth of tropical nature in insects, it being usual for only a few of the more conspicuous forms of this class to be described or illustrated; and if the Insecta can be completed in a manner at all corresponding to this first instalment, we shall have a work quite without rival in its way, and that will be pointed out as an illustration of what can be accomplished in our country and generation by the liberality and energy of private individuals. The assistance rendered to science by the publication of this volume has been supplemented by the presentation to the nation of the magnificent collection of Geodephaga accumulated by Mr. Godman for the purposes of the work; it consists of 986 species, and nearly 8000 specimens, something like 400 of the species being represented by the typical examples, and is now in the British Museum of Natural History at South Kensington.

D. S.

OUR BOOK SHELF

Outlines of Natural Philosophy. By J. D. Everett. (London: Blackie and Sons, 1885.)

"THIS book is intended to supply the widely-felt want of a work at once easy enough for a class reading-book and precise enough for a text-book." "The woodcuts with which the work is profusely illustrated are not thrown in for mere ornament, but have been carefully *designed* and selected for the elucidation of the text, and are fully explained." Had it not been for the single word which we have put in italics in the second of these extracts from the Preface, we should have at once concluded, from its general tenor, that this work was written to explain a long series of plates (most of them unmistakably French) which have already done duty in various elementary books. We were reminded of Warrington's exhortation, when he brought the proof-plate to Pendennis:—"Now, boy, here's a chance for you. Turn me off a copy of verses to this."

These plates form a wonderful collection. Some are really excellent; not only from the scientific, but even from the artistic, point of view. In others, notably Figs. 88, 93, 94, 101, 102, 130, 160, the artistic predominates over the scientific to such an extent as to render them positively misleading to the beginner. Thus in Fig. 88 the shadow of a sphere, cast by a luminous point on a plane, is drawn in such a manner as to outrage all the Laws of Projective Geometry; and the pleasing sketch Fig. 93 can only be explained (if at all) by a most peculiar state of the air over the still water. Thus, the eaves of a house are depicted as seen by reflection at a portion of the water-surface, from which (as the drawing shows) they are absolutely concealed by a hedge, while the image of the sloping roof above appears exactly as the roof itself does to the distant spectator who is nearly at the same level! Such at least must be the case, unless we make the audacious supposition that the more distant parts of this picture represent a flat surface, the drop-scene of a theatre!! Let the reader try to put his hand and its images in the aspects shown in Fig. 94; or let him try, as in Fig. 101, to see by *all but direct* reflection in a concave mirror an object situated far beyond its rim! On the other hand there are some wierd or Rhadamanthine scenes (as Figs. 134, 135, 138); and a couple at least (Figs. 99, 139) quite Lavaterian in their graphic realisation of human imbecility.

With such a frame-work or skeleton what could be expected of the book? Certainly not much; and it is so far to the credit of Prof. Everett that he has realised a fair amount of that little. But to what class of readers this book can possibly be of use, is one of those unfathomable questions which only a Mental Philosopher dares to attack. There is not, so far as we have seen, any *reasoning* in the book. Statements merely, and illustrated by pictures! To each paragraph, when the imprint of its figure-nucleus or *cliché* has been exhibited, we might append a slight but important variation of the usual mathematical formula:—

QUOD ERAT MONSTRANDUM!

The Moon, Considered as a Planet, a World, and a Satellite. By James Nasmyth, C.E., and James Carpenter, F.R.A.S., late of the Royal Observatory, Greenwich. With 26 Plates and numerous Woodcuts. (London: Murray, 1885.)

THIS is a third edition of a book which we have already reviewed in our columns. The two previous editions were issued in the quarto form, the present one is in the octavo. It is well known that this work contains the most exquisite illustrations of lunar phenomena extant. They chiefly consist of photographs of models which, when placed in the sun-light, faithfully reproduce the lunar effects of light and shadow. Lovers of astronomy are much indebted to Mr. Nasmyth for his brilliant idea, and it is to be hoped that this re-issue in a cheaper form will bring this admirable volume within the reach of many who have previously been debarred from perusing it.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Weather Forecasts

IN your number for November 2, 1882, you were kind enough to insert a letter from me on the subject of "Weather Forecasts." The letter was occasioned by what appeared to me a conspicuous failure in the forecast which was published in the newspapers for October 24. In consequence of communications which followed the publication of my letter and my own consideration of the subject, I was led to move in the House o Lords for a Return of the "Storms which have visited the British Islands between January 1, 1874, and December 31, 1883, and of which no warning has been issued from the Meteorological Office; with a Notice of the Quarter from which each Unwarned Storm has reached the Coast." This Return, which was ordered to be printed August 7, 1884, is in some respects a remarkable document. It contains a record of nearly 120 unwarned storms, or an average of nearly 12 in each year. Large as this number appears to be, I was not encouraged by the correspondence which I had with several experts to hope that much could be done to improve the system of forecasting, and I have taken no further action.

One point, however, connected with the Return appears to me to deserve notice.

On examining it I found to my surprise that the storm of October 24 was omitted altogether. This seemed to me to be strange; but my friend, the Rev. F. Redford, a well-known local meteorologist (since deceased), gave me some technical explanation of the omission with which I was compelled to rest content. In the interesting Blue-Book, however, entitled "Principles of Forecasting by means of Weather Charts, by the Hon. Ralph Abercromby," issued by the authority of the Meteorological Council, I find the failure connected with the great storm of October 24, 1882, duly chronicled and recognised. These are Mr. Abercromby's words (p. 91):—

"Our last illustration will be that of a kind which fortunately rarely occurs, viz. the sudden formation of a cyclone in an unexpected position, which entirely upsets all forecasting. In Fig. 62 [the figure is of course here omitted] we give a chart for 6 p.m., October 23, 1882. In it we see the most familar features of the westerly type of weather, and though the barometer was falling over the Bay of Biscay and rising over Scotland, there was no reason to expect that the ordinary sequence of that kind of weather would be disturbed, that is to say, that west and south-west winds, with rather showery weather, would prevail. Accordingly the following forecasts were issued."

Then follows the table of forecasts as given in my letter before referred to, and ending with "Warnings, none issued."

"When we come to look, however, at Fig. 63 [this figure here omitted], the chart for 8 a.m. the following morning, we find that a small well-defined cyclone had formed during the night over the English Channel, which moved during the day towards north-north-east, and thereby produced continuous rain with complete shifts of the wind through 180° in many parts of the country, *so that the forecasts issued were a complete failure.*"

Now, observe Mr. Abercromby's practical conclusion:—

"It may be well to consider how failures of this sort may be guarded against. The answer undoubtedly is, by taking observations at shorter intervals than fourteen hours, as on this occasion. On this particular night a halo—a sure sign that the cyclone had begun to form—was seen near London at 10 p.m., and it is therefore certain that if the observations could have been taken at 11 p m., or midnight, *such a complete failure might have been avoided.*"

These words seem to imply that something more might be done to give warning of storms. If we undertake to give these warnings, we ought not to let any question of expense stand in the way of making the warnings as complete and as correct as possible. An unwarned storm occurring on an average once a month is a serious consideration. It is not worthy of the greatest maritime nation in the world to be neglectful or niggardly in this matter.

H. CARLISLE

Rose Castle, Carlisle, November 20

P.S.—I forward herewith a copy of the Return of "Unwarned Storms."

Scandinavian Ice-Flows

REFERRING to the map in Croll's "Climate and Time," which is reproduced in his "Climate and Cosmology" (p. 133), and which traces the ice-flows of the Glacial period from the two sides of the Scandinavian peninsula, it will be seen that the said flow bifurcates in the North Sea, and that the bifurcation is at the position of the Dogger bank. I should be glad to be informed whether this fact has been observed or commented upon in any geological work.

J. D. HOOKER

Kew, November 23

Can an Animal Count?

SIR JOHN LUBBOCK, in his interesting paper on animal intelligence (NATURE, vol. xxxiii. pp. 46-7), virtually puts this question with reference to the dog. But the question whether a dog, or any other animal, can count will depend upon what we mean by counting. In the ordinary and correct signification of the term, counting consists in applying conventional signs to objects, events, &c., as when we say "one," "two," "three," to the striking of a clock. Clearly in this sense there is no reason to suppose that any animal can count. But there is another sense in which the term "counting" may be used—*i.e.* as designating the process of distinguishing, with respect to number, between the relative contents of two or more perceptions. While addressing an audience of 100 individuals a lecturer can immediately perceive that it does not contain 1000; and even without, in the true sense, counting them may make a tolerably close guess at their number. The accuracy of such a guess will depend upon two conditions. The first of these is the number of units to be computed, and the second is the previous practice he may have had in that kind of computation. Thus, every man is able to tell the difference between one and two, two and three, &c., up to perhaps seven and eight objects or events, without resorting to the expedient of marking off each with a separate sign. But somewhere about this point most persons require to adopt a system of numerical notation, if they desire to be accurate; and probably no one, without either special practice or some such system, could be perfectly sure whether he held eleven or twelve shillings in his hand, or whether a clock had just struck eleven or twelve. Indeed, it is just because of the rapidly-increasing difficulty of thus computing diminishing differences of ratio by immediate perception, that primitive man first lays the foundations of arithmetic by marking off the objects or events upon his fingers and toes. As already indicated, however, special practice makes a great difference in the accuracy with which such instantaneous computation can be made. Several years ago Prof. Preyer, of Jena, tried some experiments upon this subject, and found, if I remember correctly, that after a course of special training one might acquire the power of instantaneously distinguishing between twenty and twenty-one dots promiscuously scattered over a piece of paper.

Now, it is clearly only in this way that animals can be supposed to count at all; and, therefore, the only question is as to how far they are able to take immediate cognisance of the precise numerical content of a perception—or, in the case of a series of events, how far they are able to take similar cognisance of their past perceptions. But, as Sir John Lubbock observes, there is no record of any experiments having been made in this direction. Houzeau (tom. ii. p. 207) says that the mules used in the tramways at New Orleans are able to count five; for they have to make five journeys from one end of the tramway to the other before they are released, and they make four of these journeys without showing that they expect to be released, but bray at the end of the fifth. If this is really a case of "counting," in the incorrect sense of the term (and not due to observing some signs of their approaching release), it is probably due to their perception of a known amount of fatigue, a known duration of time, or some other such measure.

Several years ago my sister tried to teach an intelligent terrier to fetch a stated number of similar little woollen balls placed in a box at a distance from herself—the number stated, or ordered, being purposely varied from one to six. But although she is good at teaching animals, and here went to work judiciously in ways which I need not wait to describe, the result, as in the case given by Sir John Lubbock, was a total failure.

My object in making these remarks is to point out that in experiments of this kind the game seems scarcely worth the candle. Even if it were proved that a dog could "count" up to any particular number, all that we should have proved would be that the dog is able to distinguish between the degrees of two or more perceptions of a given kind; we could not thus prove any abstract conception of number on the part of the animal, such as is implied on the part of the "Damara floundering hopelessly in a calculation." Howsoever hopeless such floundering may be if the man is really *calculating—i.e.* employing some system of numerical signs—his operations are being conducted on a totally different psychological level from those of the bitch who, in surveying her litter of puppies, perceives that there is not so great a mass of them as she remembers to have perceived before. Psychologically considered, the artifice of numerical notation is as far above any such faculty of simple perception, as the artifice of alphabetical writing is above that of simple association. I cannot doubt that a moment's thought would have shown Sir John Lubbock how needless was his precaution—while establishing certain associations of ideas in a dog's mind between written words on a card and the things signified—of spelling the words phonetically, "so as not to trouble him by our intricate spelling."

It is a most interesting fact that a dog's attention can be so far fixed upon written signs that a special association of ideas admits of being established between them and the things signified; but the psychological distance between establishing such a special association and spelling a word is so enormous as not to admit of computation. And similarly, even if my sister had succeeded in teaching her terrier to fetch a stated number of balls at word of command, no one could have supposed that she had thus taught the animal to count, in the sense of employing any system of numerical notation: she would only have proved the degree in which this animal was able to perceive, *without counting*, the different appearances presented by this, that, or the other volume of balls in a box.

GEORGE J. ROMANES

Lodge's "Mechanics"

PERMIT me to thank Prof. Tait for his kind and amusing criticism of my little book. I am struck with comic horror at the thought that anything in the preface can be construed into a comparison between works like Thomson and Tait, Clerk-Maxwell and W. K. Clifford, with such elementary picture-books as Deschanel and Ganot. I do not indeed share Prof. Tait's contempt for these "foreign" books; a student will find in them details, about (say) barometers or air-pumps, for which he may search the other works mentioned in vain. I did not urge students to read Thomson and Tait, because to those who can the advice is superfluous; to those who cannot it is disheartening. I did, and do, recommend such junior students as we get at provincial colleges to read easy works on Physics—not always because they contain a profound and satisfactory statement of principles, for how few of them do, but because they explain a multitude of details and experimental developments with which it was unwise to encumber a little book dealing mainly with vital principles, and aiming at being, in its humble way, an introduction to the classics of the science.

My book is primarily intended as milk for babes; and while it would be cruel to tell a baby to look at the sun, it is possible to direct his attention to a gas-light with some pleasure and satisfaction. OLIVER LODGE

University College, Liverpool, November 13

The Resting Position of the Oyster—A Correction

IN a late number of NATURE (vol. xxxii. p. 597) Mr. J. T. Cunningham makes the extraordinary announcement that Woodward, Jeffrey, and Huxley were wrong in asserting that the oyster rests on the left side. I am in a position to state with positive certainty that it is invariably the left valve of the fry of the oyster which becomes affixed to a foreign object. I have examined thousands of very young adherent spat ranging in size from 1-90th of an inch to 2 inches in diameter, and have never found an exception to this rule. Besides the positive statements to the same effect made by Huxley and others, I would refer the reader to a brief paper by myself entitled "On the Mode of Fixation of the Fry of the Oyster" (*Bull.* U.S. Fish Commission, vol. ii., 1882, pp. 383-387); but I would caution the reader that Figs. 3 to 8 were reversed through an unfortunate oversight, as the apices of the umbos of all the larval shells figured on p. 387 should be directed to the left instead of to the right side. This blunder of the artist is pointed out in the explanation to plate 75, where the figures from the above-cited notice are reproduced in my paper entitled "A Sketch of the Life-History of the Oyster," forming Appendix II. to "A Review of the Fossil Ostreidæ of North America," by Charles A. White, M.D., and Prof. Angelo Heilprin. In another paper of mine, "The Metamorphosis and Post-Larval Development of the Oyster," Rep. U.S. Fish Commissioner, Part 10, for 1882, p. 784, Fig. 2 shows the larval shell, L, of the young spat in normal position, with the umbo directed to the left. This figure may be compared with advantage in respect to the points raised here with the figure of the external anatomy of the adult on plate 73 in my "Sketch of the Life-History of the Oyster," already cited.

Mr. Cunningham's inference that the left valve, usually regarded as the lower one, is really the upper, because he finds worm-tubes and hydroids most abundant on the convex or left valve, is founded upon an imperfect acquaintance with the habits of the oyster. For, if living oysters are thrown into the water they will invariably fall upon the bottom with the left valve downward. If dead oyster-shells—free valves—be similarly thrown into the water, they will invariably fall with the hollow side up, and the convex one down. And furthermore, both living and dead shells remain in just the position in which they fall. Dead shells sown as cultch, or collectors, fall in such a position, and most of the spat is "caught" on the exposed parts of the under surface of such shells, whereas little is found on the upper surface. The reason for this is that the sediment which is deposited on the upper surfaces, asphyxiates the young oyster-fry and the other larvæ which affix themselves before they can become established and strong enough to resist its effects. The affixed organisms on the exposed inclined under surfaces of the shells, are, on the other hand, protected from the accumulation of sediment.

It is also well known that the right valve of the oyster is always the most deeply pigmented, while the lower or left one is paler. This is always the case when oysters lie almost flat on the bottom. When crowded together on the natural banks in a vertical position, there is less difference between the colours of the valves. This difference is obviously due to some influence exerted by the position of the aspects of the body of the animal in respect to light, the same as in land and aquatic animals generally. I would conclude, for this last reason alone, that the right valve of the oyster is normally always uppermost, were it not for the fact that I have observed all the stages of transition from the spat to the adult condition in confirmation of such a conclusion. It is true that many young oysters have the right valve looking down when allowed to grow upon cultch or shells which have been sown upon the bottom to favour the collection of the spat, but that circumstance by no means subverts the conclusions of such cautious and careful observers as Brooks, Woodward, Jeffrey, Huxley, Horst, and others.

JOHN A. RYDER

Smithsonian Institution, Washington, U.S.A., November 11

The Rotation Period of Mars

ONE or two points in Prof. Bakhuysen's investigation of the rotation period of Mars require correction:—

First, my determination of the period, as finally corrected, was 24h. 37m. 22·72s., correct within 0·02s. The correction arose from the detection of a small clerical error. My final result was deduced from a comparison of observations by myself in 1873, with observations by Kaiser in 1864, Madler in 1830–1837, Sir W. Herschel in the last quarter of the eighteenth century, Huyghens and Hooke in 1666. I have since used the best observations during the oppositions of 1881 and 1883, without finding any occasion for changing my result even by one-hundredth part of a second, though I place no reliance on the second decimal figure.

But, secondly, Prof. Bakhuysen, like Mr. Denning some time since, has taken Kaiser's result uncorrected for the clerical errors—very seriously affecting it—which I detected in 1873. Kaiser counted three days too many in comparing Hooke's observation with his own: one day through a mistake in correcting for change of style, and two days (apparently) from counting the years 1700 and 1800 as leap-years. His thus taking three days too many of terrestrial time had the effect—since three corresponding Martian rotations were taken in—of introducing a deficiency amounting to three times the excess of a Martian over a terrestrial day, that is, 3×37m. 22·7s., or 67,281 tenths of a second. This, divided by the total number of Martian rotations, about 88,900, gives as a correction about 0·077s. to be added to both Kaiser's estimates, making them respectively 24h. 37m. 22·697s. and 24h. 37m. 22·668s., the mean of which, 24h. 37m. 22·6825s., is practically the same as the value I assigned, viz. 24h. 37m. 22·7s.

I think it probable that Schmidt (and perhaps Prof. Bakhuysen, too) followed Kaiser so far as the error of three days was concerned. It would naturally be taken for granted that this part of Kaiser's work was free from error. If I had not been determined to find out where and how Kaiser's calculations differed from my own, I should not have found out his mistake, for certainly one would not expect to find two large errors in a work perfectly free from small ones. But so it was. I may remark that Prof. Newcomb, of Washington, went through my calculation, finding it correct, and that Kaiser really had made the mistake I indicated.

As this correction re-established what Kaiser had doubted, the accuracy of Hooke's observations, and of my own interpretation of them, Prof. Bakhuysen's correction is scarcely admissible. For a difference of 0·06s., multiplied by 88,900 for the Martian rotations between Hooke and Kaiser in 1873, gives a total discrepancy of an hour and a half, nearly all of which must be assigned to Hooke's observations and Huyghens' (which I brought into agreement with Hooke's by correcting Kaiser's one-day error for change of style).

RICHD. A. PROCTOR

5, Montague Street, Russell Square, W.C., November 23

Beloit College Observatory

MY attention has been called to a paragraph in NATURE (vol. xxxii. p. 514), which, quoting from *Science*, speaks of "the Astronomical Observatory of Beloit College as closed for lack of funds." It is not strange that you express surprise at this announcement. Permit me to say that it is positively untrue. So far as I can learn, the only authority for it is a strange and entirely unwarranted statement from our late Director. Mr. Tatlock's connection with our Observatory closed on July 1 last. Within one week of that date Mr. Charles A. Bacon was appointed his successor, and a few weeks later he appeared and took charge. He has already proved himself competent, both as an observer and as an instructor. New arrangements are made for both meteorological and astronomical observations, and special attention will be given to solar and spectroscopic work. Though not richly endowed, our "Smith Observatory" is well equipped, and under its present direction its facilities will be made helpful to both the advancement and the diffusion of science. A. L. CHAPIN

Beloit College, Wisconsin, October 31

CONFERENCE OF DELEGATES OF CORRESPONDING SOCIETIES OF THE BRITISH ASSOCIATION, HELD AT ABERDEEN

A NEW branch of the British Association glided unobtrusively into existence at Aberdeen, under the new rules passed in the previous year: I mean the Conference of Delegates of Corresponding Societies. The Committee to whom the general arrangements connected with this new branch is intrusted are now issuing a circular to the Corresponding Societies, signed by myself as its Chairman, and by Prof. Meldola as its Secretary, in which they give an account of the proceedings at Aberdeen, with comments thereon. Much of this will be of general interest, as it helps to explain the functions of the Conference, which, as the proceedings showed, were imperfectly understood by many of the delegates themselves. The report is too long to ask you to print it in full, and on the other hand its general purport is more easily seized by leaving out details. I therefore limit myself to sending you extracts from it, with connecting-links of explanation to make them read continuously.

The Corresponding Societies Committee of the British Association beg to lay the following statement of work done at Aberdeen, with comments thereon, before the Presidents and Councils of the various Societies whose applications for enrolment as Corresponding Societies of the British Association had been granted.

The Conference of Delegates was held on Thursday, September 10, and on Tuesday, September 15, both meetings having been called at 3.15 p.m., and lasting in each case about one hour.

(Here follows a list of the various Corresponding Societies and of the attendance of their respective representatives.)

At the first meeting

The Secretary read the first report of the Corresponding Societies Committee, which had been presented to the Council and accepted by the General Committee of the British Association. Methods of procedure were then discussed, and explanations as to the functions of the Conference were given by the Chairman and Secretary in reply to questions or otherwise.

After some informal conversation, invited by the Chairman for an interchange of views, in which suggestions were made as to the nature of the work which might be taken up by Local Societies,

The Chairman explained that although individual delegates might perhaps like to take advantage of the Conference to mention informally and when time permitted, any work in which their Society was engaged, with the object of comparing views with, or obtaining assistance from, their brother delegates, it did not fall within the functions of the Conference to suggest or to initiate any scheme of local investigation. It was their function simply to consider how such schemes of the kind, as had been previously considered and adopted by the British Association, through its General Committee, could be best carried out. If any delegate desired to formally propose to the Conference any subject for local investigation, he must do so through the regular channels along which all proposals that receive the sanction of the British Association have to pass. In such cases the subject must first be brought before the Committee of the Section within whose province it lies. It is for that Sectional Committee in the first instance to discuss its merits, and if they approve of the idea they will forward it, backed with their approval, to the Committee of Recommendations, whose duty tt is to revise all such proposals, especially when they involve grants of money, and to submit them in their revised form to the General Committee, under whose sanction they become invested with the full authority of the British Association. Every proposal that has been approved by a Sectional Committee, and is concerned with local investigation, will be forwarded under the new rules by the Secretary of the Section to the Secretary of the Conference, at the same time that he forwards it to the Committee of Recommendations. The hour and day of the meetings would not admit of delaying the consideration of the proposals by the Conference until they had passed through their final stages and had received the formal sanction of the Association, but practically little or no difficulty will arise from this forestallment of their final approval, because it is a matter of experience that the deliberate approval of a Sectional Committee is rarely over-ruled on after-consideration, except it be on the grounds of finance, in which case the investigation would simply be abandoned. The real point of importance is that every proposal should pass its first and principal ordeal before a Sectional Committee before it becomes admissible as a subject of formal consideration by the Conference of Delegates. He also reminded the Conference that, in accordance with Rule 7 of the rules relating to Corresponding Societies, "The Conference may also discuss propositions bearing on the promotion of more systematic observation and plans of operation, and of greater uniformity in the mode of publishing results."

At the second meeting of the Conference the following recommendations for the appointment of Committees intrusted with local inquiries were read to the Conference:—

(1) For the purpose of defining the racial characters of the inhabitants of the British Isles. Dr. Garson explained the objects of this Committee, and invited the co-operation of the Local Societies.

(2) For the purpose of recording the position, height above the sea, lithological characters, size, and origin of the erratic blocks of England, Wales, and Ireland, reporting other matters of interest connected with the same, and taking measures for their preservation.

(3) For the purpose of investigating the circulation of the underground waters in the permeable formations of England, and the quality and quantity of the water supplied to various towns and districts from these formations.

(4) For the purpose of inquiring into the rate of erosion of the sea-coasts of England and Wales, and the influence of the artificial abstraction of shingle or other material in that action.

Mr. C. E. De Rance made brief statements explanatory of the work of each of the three foregoing Committees, and pointed out the manner in which assistance could be rendered by the Local Societies.

A letter was read from the Secretary of Section D, transmitting a recommendation that the subject of the preservation of the native plants of this country should be brought under the notice of the Local Societies, and deputing Prof. W. Hillhouse to bring this subject before the delegates present at the Conference.

In accordance with the foregoing recommendation, Prof. Hillhouse gave numerous instances of the extermination of rare plants from certain localities by dealers, to whom their habitat had become known. He stated that, having been empowered by the Sectional Committee to represent their views on this subject, he had thought it desirable to draw up the following protest:—

"We view with regret and indignation the more or less complete extirpation of many of our rarest or most interesting native plants. Recognising that this is a subject in which Local Societies of naturalists will take great interest, and can exercise especial influence, we urge upon the delegates of Corresponding Societies the importance of extending to plants a little of that protection which is already accorded by legislature to animals and prehistoric monuments, and of steadily discouraging and, where possible, of preventing any undue removal of such plants from their natural habitats; and we trust that they will bring these views under the notice of their respective Societies."

It was then arranged: (1) That the above gentlemen (or, if more convenient, the Chairman or the Secretary of the Committees they severally represent) should communicate with each of the delegates as soon as the details of their proposed investigations had been matured. (2) That each delegate should thereupon do his best to interest the members of his Society, and, if thought desirable, the Society itself, in the subject of investigation, and should send to his correspondent the names and addresses of such persons in his neighbourhood as might be likely to render willing and effectual help, so as to put him at once in direct communication with them.

It was further agreed that, with the view of making the delegates personally acquainted with one another, it was advisable to give them an opportunity of dining together at an early day during the meeting, and Prof. Meldola was authorised to make the necessary arrangements for the following year at Birmingham. Thursday was suggested as a convenient day for the dinner, but it seems better on reconsideration to adopt Wednesday, at 6. After the dinner the delegates would proceed to the places reserved for them at the opening evening meeting to hear the President's address. Particulars of the place and cost of the dinner, &c., will be posted on the notice board in the reception room.

The Corresponding Societies Committee have now to point out that, although thirty-nine Societies were admitted as Corresponding Societies, only twenty-three of them nominated delegates. Of the twenty-three delegates only eleven were present at the final meeting to hear the explanations of the gentlemen who attended for the purpose of making them, and of placing themselves in personal communication with the several delegates. The Committee feel sure that the delegates who failed to attend the Conference had not realised the character of the engagement into which they had entered, and that they must have erroneously regarded their title and privileges as purely honorary, and their duties as sinecures. The Corresponding Societies Committee desire it to be clearly understood that such is not the case, as the work intrusted to the delegates is real and important. Conspicuous notices of the times and place of meeting of the Conference had been posted in prominent positions in the reception room and in the sectional rooms, so that ignorance of the meetings could hardly be pleaded in excuse. The position of each delegate is that of a person of scientific influence in his own neighbourhood, who, by the acceptance of his title and its privileges, pledges himself to act as a friendly intermediary between those Committees of the British Association who are occupied with local investigations and the local scientific men who are known to him. It is his duty to make himself well informed of the nature of the proposed inquiries sanctioned by the British Association as personally explained by the representatives of the respective Committees, and to qualify himself as far as possible for the honourable post of local correspondent. It is in return for the prospect of this very valuable assistance that the position of a member of the General Committee is granted to each delegate, and the privilege is accorded of having published in the *Reports* of the British Association a catalogue of the local investigations of the Society which he represents. Hereafter the Corresponding Societies Committee will take into consideration the advisability of not recommending for re-election those Societies whose delegates fail to attend the meetings of the Conference without adequate explanation.

These views were expressed by the Chairman at the second meeting of the Conference, and they appeared to be fully in harmony with the feelings of the delegates who were present.

The above extracts contain all that is of general importance in the circular letter. Whether or no the Conference of Delegates will grow into an important branch of the British Association remains to be seen. The rules under which it is established ought to secure it from the danger of provoking the jealousy of Local Societies by the assumption of a dictatorial attitude towards them and by interfering in their concerns; on the other hand they as surely prevent it from growing into the anomalous office of an *imperium in imperio* as regards the British Association. Consequently the success of the Conference appears wholly to depend on an abundant and continuous supply of good work being found for it to do, and on a sufficiency of zeal among the delegates to perform their duties efficiently.

FRANCIS GALTON

DR. CARPENTER, C.B., F.R.S.

A SHORT sketch of the life and work of the eminent naturalist who has recently passed from among us will be welcome to the readers of NATURE.

William Benjamin Carpenter was born at Exeter in 1813, and was the fourth child and eldest son of Dr. Lant Carpenter, a Unitarian minister. His sister, Mary Carpenter, who died a few years since, achieved the most important work as a philanthropist, in relation to the treatment of prisoners and to questions affecting our Indian fellow-subjects, and will be remembered by future generations with no less gratitude than her brother.

In his childhood Dr. Carpenter received an excellent education, comprising both classics and the principles of physical science, at the school established by his father at Bristol, and it was his intention to adopt the profession of a civil engineer. He was, however, persuaded to accept the opportunity offered by a medical practitioner, Mr. Estlin, of Bristol, and to enter on the study of medicine as apprentice to that gentleman. Shortly after this he was sent, as companion to one of Mr. Estlin's patients, to the West Indies, and on his return from this visit he entered, at the age of twenty, the medical classes of University College, London. After passing the examinations of the College of Surgeons and the Apothecaries' Society he proceeded to Edinburgh, where he graduated as M.D. in 1839.

His graduation thesis on "The Physiological Inferences to be deduced from the Structure of the Nervous System of Invertebrated Animals" excited considerable attention, especially on account of the views which he advanced as to the reflex function of the ganglia of the ventral cord of Arthropoda.

From the first Dr. Carpenter's work showed the tendency of his mind to seek for large generalisations and the development of philosophical principles. He was a natural philosopher in the widest sense of the term—one who was equally familiar with the fundamental doctrines of physics and with the phenomena of the concrete sciences of astronomy, geology, and biology. It was his aim, by the use of the widest range of knowledge of the facts of Nature, to arrive at a general conception of these phenomena as the outcome of uniform and all-pervading laws. His interest in the study of living things was not therefore primarily that of the artist and poet so much as that of the philosopher, and it is remarkable that this interest should have carried him, as it did, into minute and elaborate investigations of form and structure. Although some of his scientific memoirs are among the most beautifully illustrated works which have been published by any naturalist, yet it is noteworthy that he himself was not a draughtsman, but invariably employed highly skilled artists to prepare his illustrations for him. Yet we cannot doubt that the man who, with his dominant mental tendency to far-reaching speculations, yet gave to the world the minute and ingenious analysis of the beautiful structure of the shells of Foraminifera, had an artist's love of form, and that the part of his life's work (for it was only a part among the abundant results of his extraordinary energy) which was devoted to the sea and the investigation of some of its fascinating living contents, was thus directed by a true love of Nature in which ulterior philosophy had no share.

Two books, Dr. Carpenter has told us, exerted great influence over his mind in his student days: they were Sir John Herschel's "Discourse on the Study of Natural Philosophy" and Lyell's "Principles of Geology"—that great book to which we owe the even greater books of Charles Darwin. Taking the "Principles" in some way as his model, Dr. Carpenter produced in 1839 his first systematic work, under the title "Principles of General and Comparative Physiology, intended as an Introduction to the Study of Human Physiology and as a Guide to the Philosophical Pursuit of Natural History." Admirable as was the execution of this work in many ways, its great merit lay in the conception of its scope. It was in fact the first attempt to recognise and lay down the lines of a science of "Biology" in an educational form. Carpenter's "Comparative Physiology" is the general or elementary "Biology" of the present day—traced necessarily upon the less secure foundations which the era of its production permitted, viz. one year only subsequent to the date of Schwann's immortal "Microscopical Researches."

For five years Dr. Carpenter remained in Bristol, commencing medical practice and marrying in 1840; but in 1844, feeling a distaste for the profession of medicine, he removed to London in order to devote himself entirely to a literary and scientific career. He was encouraged to take this step by the success which his "Comparative Physiology" obtained, a second edition having been called for within two years of the publication of the first. He was appointed Fullerian Professor of Physiology in the Royal Institution during his first year in London, and Professor and Lecturer at University College and at the London Hospital, whilst he was also elected a Fellow of the Royal Society.

In 1851 Dr. Carpenter became Principal of University Hall, the residential institution attached to University College, where he remained until 1859. During this period he remodelled his treatise on Physiology, issuing the more general biological portion as "Comparative Physiology," whilst that portion dealing with the special physiology of man and the higher animals appeared as his well-known "Human Physiology," which subsequently ran through many editions. The "Human Physiology" is remarkable in the first place for the chapters on the physiology of the nervous system, and especially for the theories enunciated with regard to the relations of mind and brain, and the attempt to assign particular activities to particular portions of the cerebral structure. In arriving at his conclusions Dr. Carpenter had to depend on arguments drawn from the facts of comparative anatomy and of diseased or abnormal conditions in man. There is no doubt at the present day of the acuteness which he displayed in his treatment of the subject, and of the truth in a general way of the results which he formulated. Experiment and a wider range of observation have to some extent corrected—but on the whole rather extended and confirmed—the doctrines of the early editions of the "Human Physiology" in regard to this subject, so that he was able only a few years since to separate this portion of the work and issue it as a separate book, the "Mental Physiology," in which is contained by far the most complete, consistent, and readable account of the phenomena of mind, and their relation to the actual structure of the brain, which exists. Such topics as Instinct, Mesmerism, Somnambulism, Unconscious Cerebration (his own phrase), &c., are discussed in a masterly way, and with an abundance of illustration and knowledge which renders the work one of the greatest value even to those who may differ there and there from its theoretical conclusions.

About the period of his removal to London Dr. Carpenter began to occupy himself with the minute study of the structure of the calcareous shells of the Mollusca—being led thereto by a desire to compare the results of the operation of living matter upon distinctly mineral compounds (such as carbonate of lime), by way of comparison and in illustration of the rapidly accumulating knowledge of cell-structure in the softer parts of living things. This study, which resulted directly in some valuable contributions to our knowledge of the structure of shells, shown by these researches to be far more complex than had hitherto been supposed, led on the one hand to Dr. Carpenter's permanent identification with the pursuit of research with the microscope, and on the other hand to those admirable investigations of the structure and law of growth of the shells of the minute Protozoic Foraminifera which constitute his most weighty contribution to the special literature of science. His microscopic studies bore fruit in the publication of "The Microscope and its Revelations," the sixth edition of which was issued in 1881. The studies on the shells of Foraminifera were continued throughout his life, being published in four memoirs in the *Philosophical Transactions*, and in a richly illustrated monograph produced by the Ray Society in 1862, whilst the last of his memoirs in the *Philosophical Transactions* was that on Orbitolites bearing date so late as 1882. It was on this subject that Dr. Carpenter was busy at the time of his death, having during the past few years accumulated a wealth of material and drawings in support of his contention that the *Eozoon canadense* discovered by Logan in the Laurentian rocks of Canada exhibits the distinctive structure of the shell-substance of the higher Foraminifera. There is reason to hope that the memoir which he had nearly completed on this subject may yet be brought by his son, Dr. Herbert Carpenter, into a finished form and published.

At the age of forty (1853), what with his larger and smaller books, his original researches, his lectures on medical jurisprudence at University College, and numerous popular lectures on scientific topics, Dr. Carpenter's life was unusually laborious and productive.

In 1856 he was appointed Registrar of the University of London, and for twenty-three years administered the onerous duties of that office in such a way as to contribute in no small degree to the success of the University, and above all to the maintenance of the high character of its degrees and the ample recognition of the study of natural science for which the University is now distinguished.

He was able now to give a larger amount of time than formerly to his original investigations, and, in his summer holidays at Arran and elsewhere, commenced, amongst other studies, those researches on the structure and development of the beautiful little feather-star, which were from time to time published in the *Philosophical Transactions*, and led to his association with Wyville Thomson, and thus to the deep-sea explorations of the *Lightning*, and subsequently of the *Challenger*.

Carpenter's memoirs on Comatula give a very full and beautifully illustrated account of the structure of the skeleton of the feather-star, but for many years the view which he entertained with regard to the nature of the axial cord which runs through the segments of the arm-skeleton of that animal was regarded by all other observers (with scarcely an exception) as erroneous. Dr. Carpenter considered these cords as nerve-cords, and after his retirement from official life he made a special visit (only five years or so ago) to the marine laboratory erected by Dr. Dohrn at Naples, in order to test his views by the repetition, on an extensive scale, of experiments which had already appeared convincing to his mind. These experiments, and others since carried out by younger naturalists, have at length fairly established the view for the truth of which the veteran observer had long contended.

The deep-sea explorations which Dr. Carpenter, assisted by Prof. Wyville Thomson, arranged, and for which he succeeded in obtaining the aid of ships of the Royal Navy, were designed not merely to search for organisms in the great depths of the ocean, but especially to study the ocean currents both deep and superficial, Dr. Carpenter having a strong desire to enter upon the explanation of the great physical phenomena presented by the ocean. He himself took part in the earlier expeditions in 1868 and subsequent years, and though unable to leave the ties which bound him to home, so as to join the long *Challenger* Expedition, yet he closely watched the results then obtained, and embodied the whole of his observations, and those reported from the *Challenger*, in some extremely suggestive and important memoirs and lectures on ocean circulation.

In 1879 he retired from the Registrarship of the University of London with a well-earned pension, and was at once chosen as a member of the Senate of that body. He now devoted himself with unabated vigour to the prosecution of his studies on Foraminifera and on Comatula, and to more theoretical matters, such as ocean-currents, and the explanation of the frauds of spirit-mediums. Though released from the duties of office, he was still a constant attendant at the Senate of the University, he rarely missed a meeting of the Royal Society or one of the annual gatherings of the British Association, and, besides undertaking the administration of the Gilchrist trust, delivered many lectures in all parts of the country himself—both independently and as an emissary of the trustees. The scheme of lectures and scholarships instituted by the Gilchrist trustees, which is effecting an important educational work in natural science among classes of society excluded from regular University teaching, is Dr. Carpenter's work. He wrote at this time in the interest of the public health some admirable articles on vaccination, as in earlier life (1849) he had from a similar point of view treated the subject of alcoholic liquors, and had urged the arguments for total abstinence. When past seventy years of age he did not shrink from a journey to the United States, where he spoke and lectured with unflagging vigour. The last public movement in which he took an active part was the foundation of the Marine Biological Association, of which he was a Vice-President, and which is about to carry out, by means of its laboratory on Plymouth Sound, a suggestion which is traceable to his own proposition for the thorough exploration and study of Milford Haven.

The abundant and noble achievements of Dr. Carpenter's public and scientific career did not pass without recognition in the form of awards and titles. He received in 1861 one of the Royal medals awarded by the Council of the Royal Society, and in 1883 the Lyell medal of the Geological Society. In 1871 he was made an honorary LL.D. of the University of Edinburgh, and in 1872 he was President of the British Association for the Advancement of Science, when it met at Brighton. In 1873 he was elected Corresponding Member of the Institute of France, and on his retirement from his official position at the University of London in 1879 he was nominated C.B.

It is impossible to do justice to Dr. Carpenter's character as a scientific man in a few lines: here no attempt has been made to do more than indicate in something like chronological order and connection of subjects the vast amount of work which he accomplished.

Upon the present writer, whose father was his fellow-student at University College, and who has enjoyed since boyhood the privilege of his friendship, Dr. Carpenter always produced the most vivid impression of a man of indomitable energy, who had accepted as the highest duty and keenest delight of his life, the promotion, whether by advocacy or by research, of true knowledge. The tenacity and vigour with which he was wont to expound his views on such matters of research as at the time occupied his thoughts, and the importance and respect which he assigned to all genuine research, were evidences of an earnest and just nature which evoked sympathy and esteem in all men of kindred pursuits.

In reference to Dr. Carpenter's private life and tastes, the following extract from a weekly contemporary states, with the authority of a member of his own family, what might, in its absence, have been here less completely indicated. The journal to which we are thus indebted is an organ of the Unitarian Church, of which body Dr. Carpenter was, throughout life, an active and orthodox member, a fact which may or may not be brought into connection with the fact of his incomplete acceptance of the leading doctrines of Darwinism, though the latter would by no means necessarily follow from the former.

"He was well versed in literature, and turned for refreshment in hours of weariness to his favourite Scott. Political memoirs of his own time were read with the keenest relish, for he had early learned from his father, Dr. Lant Carpenter, to take a high view of a citizen's obligations, and the Bristol riots, which he had witnessed, made a life-long impression upon him. A brief sojourn in Italy called forth a susceptibility to the enjoyment of art, which was a surprise even to himself; and in music, from the time that he had taught himself as a young man to play on the organ, he found unfailing recreation. Nature, likewise, in her vaster as well as her microscopic forms, was for him full of charm and delight, and from every excursion he carried back memories which remained singularly vivid and distinct. In society his immense stores of information, his sympathetic interest in others, his thorough enjoyment of humour though he felt unable to originate it, made him a genial and ever-welcome companion, while his friends learned how strong a confidence might be placed in his faithfulness. Many young men found unexpected help and encouragement in him, and he rejoiced when he could open a way to those who were involved in the struggles through which he had himself once passed. The dominant conception of his life—as was fitting in one of Puritan descent—was that of duty. And if this sometimes took austere forms, and led him to frame expectations which others could not always satisfy, an enlarging experience mellowed his judgment and enabled him to apprehend their position from their point as well as his own. Released from the pressure and strain of earlier life, he was able to give freer play to his rich affections; and in his own family they only know what they have lost who will never again on earth feel his support as husband and father, brother, and friend."

E. RAY LANKESTER

WALTER FLIGHT, D.Sc., F.R.S.

THE close of this year has witnessed the termination of another bright and promising life, ended all too soon for the hopes and expectations of his many friends.

Walter Flight was the son of William P. Flight, of Winchester, in which city he was born on January 21, 1841. He was sent, after a period of pupilage at home, to Queenwood College, Hampshire, in the days when George Edmondson was head master, and Tyndall and Debus were the teachers of science. From Queenwood he went to the University of Halle, where, in the laboratory of Prof. Heintz, he pursued his chemical studies during the winter session of 1863-64. During 1864 and 1865 he entered the University of Heidelberg, where, in the laboratories of the celebrated Profs. Bunsen, Kopp, and Kirchhoff, he applied himself early to acquire that thorough knowledge of the various branches of theoretical and practical chemistry, and that marked facility for overcoming experimental difficulties which characterise the practised and careful worker. From Heidelberg Flight passed to the University of Berlin, where he remained until 1867, studying and working in Prof. Hofmann's laboratory, and for a time filling the office of his Secretary and Chemical Assistant.

Returning to England in 1867, he graduated D.Sc. in the University of London, and in the following year was appointed by the Senate to the office of Assistant Examiner under Prof. Debus (his former teacher at Queenwood). On September 5, 1867, Dr. Flight was appointed an Assistant in the Mineralogical Department of the British Museum. Here, under the direction of Prof. Maskelyne, the Keeper of Mineralogy, he commenced a series of researches into the chemical composition of the mineral constituents of meteorites and the occluded gases they contain. Many of the methods by which he carried out these investigations were originated by him in the course of the research, and displayed in a remarkable degree his skill and ingenuity in chemical manipulation.

He was shortly after this date appointed Examiner in Chemistry and Physics at the Royal Military Academy, Woolwich, and in 1876 Examiner to the Royal Military Academy, Cheltenham.

For several years Dr. Flight served on the Luminous Meteors Committee of the British Association, to which he lent much valuable assistance.

Between the years 1864 and 1883 he was author of twenty-one original papers, including "A Chapter in the History of Meteorites," which appeared in a succession of twenty-three articles in the *Geological Magazine* in 1875, 1882, and 1883. He was also joint author or contributor of results to many other papers, chiefly on the chemical composition of minerals. His important memoir on the Cranbourne, Rowton, and Middlesbrough meteorites was read before the Royal Society in 1882, and he was elected a Fellow in the following year.

In 1884 he was seized by illness which prostrated his mental powers, and rendered it needful for him to resign his appointment in the British Museum in June last, and notwithstanding every care which medical skill or affection of friends could devise, he succumbed on November 4, leaving a wife and three young children to deplore his early loss.

ON RADIATION OF HEAT FROM THE SAME SURFACE AT DIFFERENT TEMPERATURES

FOR some time past I have been engaged in experimenting on the radiation of heat from the surfaces of wires in air and in vacuum, and I have obtained results which have been partially communicated in papers to the Royal Society (1884) and to the British Association at its last two meetings. I am at present preparing to publish further determinations of emissivities in absolute measure. In the meantime, however, I have obtained a result of some importance which may be of interest to the readers of NATURE.

Stefan has given a law, which is well known, as to the dependence on temperature of radiation of heat from the same surface—namely, that the radiation is in proportion to the fourth power of the absolute temperature. This law was deduced originally from certain experiments of Prof. Tyndall on radiation from a heated platinum spiral (*Pogg. Ann.*, Bd. cxxiv., quoted by Wüllner, "Exp. Physik," Bd. iii. 1885). The law has been also considered by other writers, including Christiansen (*Ann. der Physik und Chemie*, Bd. xix. 1883), and they have adduced experiments which seemed to them to confirm it.

The method of experimenting which I employ makes it easy to test the truth of such a law, and in fact to find the law, and I have accordingly made the necessary calculations for the former purpose.

In my experiments a current of known strength is passed through the wire under examination, and the increase in the resistance of the wire due to heating by the current is determined while the current is passing through it. When the temperature of the wire has become constant, the heat generated by the current (which can be calculated in absolute measure) must be equal to that emitted by the surface of the wire *plus* that lost at the ends of the wire by conduction. The temperature of the wire at the moment is also ascertained from its resistance (as was done by Siemens in his experiments on resistance of platinum wire at different temperatures, *Proc.R.S.*, vol. xix. p. 443). I have recently been experimenting on platinum wires in a high vacuum down to about 1/20 **M**. (one twenty-millionth of an atmosphere), as was described to the British Association at its meeting at Aberdeen.

The results quoted in Table I. below were obtained with a straight platinum wire about half a metre long, 0·04 cm. in diameter. It was contained in a glass tube about 0·6 cm. in internal diameter, and was sealed into the tube at the two ends, the exhaustion being made by a small side tube. The exhaustion at the time of the experiment, as measured by a McLeod gauge, was 1/15 **M**. The temperature of the room during the experiment was 15° C.

The following two tables show the results of the experiment, and also a comparison of these results with the increase of emissivity with absolute temperature calculated according to Stefan's supposed law. Four cases have been taken which are numbered in the first column of each table. For these the current, C, and the resistance of the platinum wire, R, as found by experiment, are given in the second and third columns of Table I. The energy lost by the wire, C^2R, called e in Table II., and the estimated temperature Centigrade are given in the fourth and fifth columns of Table I. The temperature of the surroundings at the time of the experiment was 15° C. In the second table, the second, third, and fourth columns show the absolute temperatures of the wire and surroundings, and the energy lost, e, or C^2R. Column 5 shows the ratios of the energy lost in the several cases to that lost in Case 1, taken as unity. According to Stefan's law the heat emitted from the wire ought to be given by

$$W = A(S^4 - T^4),$$

where S is the absolute temperature of the wire, and T that of the surroundings. Hence if S_1, T_1 denote those temperatures in Case No. 1, and if the heat emitted in this case be taken as unity, the heat emitted with any other temperatures, S and T, would be

$$\frac{S^4 - T^4}{S_1^4 - T_1^4}.$$

This ratio, for the temperatures of the several cases, is given in the sixth column of Table II.; and it will be seen by comparison with Column 5 of that table that the increase of loss of heat with increase of temperature does not follow any such exceedingly rapid law.

TABLE I.—*Results of Experiment*

Case	Current C	Resistance R	Energy emitted C^2R	Temperature, Centigrade °	Condition of wire
1	1 × 0·169	1·087	1·087	25	
2	2·2 × ·169	1·371	6·636	110	
3	6 × ·169	2·17	78·12	525*	Wire perceptibly red in the dark
4	6·5 × ·169	2·32	98·06	550	Wire distinctly red hot

* Temperature 525° taken according to Draper's estimate of temperature of a body just visible in the dark.

TABLE II.—*Comparison of Experimental Results with Calculation in accordance with Stefan's Law*

Case	Absolute temperature of wire (S)	Absolute temperature of surroundings (T)	Energy emitted (e)	Ratio e/e_1	Ratio $\frac{S^4 - T^4}{S_1^4 - T_1^4}$
1	298	288	1·087	1	1
2	383	,,	6·636	6·1	16
3	798	,,	78·12	71·9	438·8
4	823	,,	98·0	90·2	499·8

A comparison between the last two columns shows the enormous discrepancy between the results calculated from Stefan's law and those obtained by experiment.

I am now waiting for the use of a secondary battery, which I expect to have in a very short time, to determine the ratio between the energy lost at dull red heat, say 550° C., and that lost at bright white heat (1200° C. according to Draper), for the case of an incandescent lamp. Already, however, we know enough of the behaviour of incandescent lamps—for example, in the case of an eight-horse-power gas-engine, developing five-horse-power of electric energy, and feeding 50 sixteen-candle-power lamps—to be able to say that it does not require ten times as much work to keep the lamps at white heat as it does to keep them at dull red heat.

November 16 J. T. BOTTOMLEY

ELLIPTIC SPACE

ELLIPTIC geometry is more general than ordinary geometry. It refers to a three-dimensional space of a more general type than ordinary space. The ordinary mathematics supposes a more or less plausible assumption or axiom which reduces elliptic space to a special type. The present little paper is intended to illustrate the unartificial character of the elliptic geometry and to indicate the analytical nature of the axiom which the Euclidian geometry requires us to introduce. We investigate the *measurement of distance* on which the theory of elliptic space chiefly depends.

It is requisite to observe carefully the definitions which are made, and to refrain from the introduction of any notions not explicitly conveyed by the definition. Let us consider a "point" whose co-ordinates are x_1, x_2, x_3, x_4. It is not necessary to think of these co-ordinates as related to any geometrical scaffolding of tetrahedra or the like. It is in fact desirable to attach no geometrical import to the words, and merely to think of the word "point" as implying the four magnitudes just written. A second "point," y, will be similarly denoted by $y_1\ y_2$, y_3, y_4, and we *define* that the point x is distinct from y, unless in the case where

$$\frac{x_1}{y_1} = \frac{x_2}{y_2} = \frac{x_3}{y_3} = \frac{x_4}{y_4}.$$

If λ be a numerical magnitude

$$x_1 + \lambda y_1,\ x_2 + \lambda y_2,\ x_3 + \lambda y_3,\ x_4 + \lambda y_4$$

will also denote a point, and then, it being assumed that x and y are distinct, we have a multitude of points corresponding to the various values of λ. This series we call a "straight line." But we here make no implication of any geometrical character attached to the line. It is merely a collocation of points, where each point is a group of four symbols and nothing more.

Each point on the line is thus correlated with a specific value of the numerical magnitude λ, and thus if we have two points we may refer to them as the points λ and μ respectively.

As we are free from any geometrical meaning of our symbols, we can only introduce the expression "distance between two points" by defining precisely what is meant. The distance will be a function of λ and μ, whose form is to be decided by the properties which we desire to attribute to it. We may therefore select certain laws which we desire this function shall obey, and then discover what function will satisfy the conditions necessary.

We may take a hint from our familiar geometry as to the conditions to be imposed upon the distance function. If A, B, C be three points upon a straight line, then there is no more fundamental notion of distance than that implied in the equation

$$AB + BC = AC.$$

We shall accordingly insist that our distance function shall be obedient to this law (which we may call Law I.). If, therefore, λ, μ, ν be three points upon our straight line, and if $f(\lambda, \mu)$ denote the distance from λ to μ, then we find

$$f(\lambda, \mu) + f(\mu, \nu) = f(\lambda, \nu),$$

and as μ must disappear from this equation we have

$$f(\lambda, \mu) = \phi(\lambda) - \phi(\mu).$$

The first step in the construction of an appropriate distance function has thus been taken, but we have still a wide range of indeterminateness, for $\phi(\lambda)$ may of course be any conceivable function of λ. It will therefore be competent for us to select some additional law and to insist upon obedience to it also.

Again we revert to our familiar geometry for a suggestion. In that geometry it is assuredly obvious that the distance between two points cannot be zero unless the two points are coincident. Trite as this condition may appear, it is yet sufficient to clear every trace of indeterminateness from the form of ϕ: we shall term this Law II.

Combining Laws I. and II. it will be easy to show that if P be a point on the line then there can only be one point, Q, on the line at a given distance from P, for, suppose that there was a second point, Q', then we have, by Law I.,

$$PQ + QQ' = PQ';$$

but if PQ be equal to PQ', then

$$QQ' = 0,$$

from which, by Law II., we see that Q and Q' must be identical.

If the point P be defined by λ, and the point Q at a given distance therefrom be defined by μ, then the relation between λ and μ must be of the one-to-one type. The distance given, we must therefore have some equation of the form

$$A\lambda\mu + B\lambda + C\mu + D = 0.$$

Any constant values for A, B, C, D will be consistent with the conditions, but we can without loss of generality simplify this equation. If we make $\lambda = \mu$ we obtain the quadratic

$$A\lambda^2 + (B + C)\lambda + D = 0.$$

We thus see that there are in general two critical points on the line corresponding to the roots of this equation. If we choose these two points for x and y, which is of course possible without sacrifice of generality, the roots of this equation should be 0 and ∞, or in other words the constants A and D must be each zero. We thus see that by an appropriate choice of the fundamental points the relation between λ and μ assumes the simple type

$$B\lambda + C\mu = 0,$$

or, finally,

$$\lambda = h\mu,$$

in which h is a function of the particular distance between λ and μ.

We have, however, seen that the distance is also to be expressed in the form

$$\phi(\lambda) - \phi(\mu).$$

This must therefore be a function of h, that is, of $\lambda \div \mu$, and thus we have

$$\phi(\lambda) - \phi(\mu) = F\left(\frac{\lambda}{\mu}\right).$$

From this equation the particular value of the distance has disappeared. It must therefore be true for all values of λ and all values of μ. It must remain true if differentiated either with respect to λ or μ. We therefore have

$$\phi'(\lambda) = \frac{1}{\mu} F'\left(\frac{\lambda}{\mu}\right)$$

$$-\phi'\mu = -\frac{\lambda}{\mu^2} F'\left(\frac{\lambda}{\mu}\right),$$

whence

$$\lambda\phi'(\lambda) = \mu\phi'(\mu),$$

but as λ and μ are independent this requires

$$\phi'(\lambda) = \frac{H}{\lambda},$$

or

$$\phi(\lambda) = H \log \lambda,$$

whence finally we see that the distance between the two points λ and μ is

$$H \log \frac{\lambda}{\mu},$$

where H is a constant.

There seems nothing arbitrary in this process. We have set out with the two laws I. and II., and we have without any other assumption been conducted to the logarithmic conception of distance which lies at the foundation of the elliptic geometry. We might almost be tempted to ask how any other conception of distance can be reasonable. The two laws assumed are obviously true on any intelligible conception of distance, and yet they conduct to the logarithmic expression and apparently to nothing else.

It remains to show where the assumption made in ordinary geometry comes in. Hitherto we have not restricted the generality of the constants A, B, C, D which enter into the equation between λ and μ. Euclid, however, demands that the expression

$$(B + C)^2 - 4AC$$

shall be equal to zero. This has the effect of rendering the quadratic equation a perfect square. The logarithmic theory is accordingly evanescent, and we have to resort to the specialised conception of ordinary distance.

ROBERT S. BALL

NOTES

THE Council of the Royal Society at their last meeting awarded the Copley Medal to Auguste Kekulé, of Bonn (For. Mem. R.S.), for his researches in organic chemistry, and the Davy Medal to Jean Servais Stas, of Brussels (For. Mem. R.S.), for his researches on the atomic weights. At the same meeting, Prof. D. E. Hughes, F.R.S., and Prof. E. Ray Lankester, F.R.S., were nominated for the Royal Medals—the former eminent for his electric researches, and the latter for his services to embryology and animal morphology. Her Majesty has since signified her approval of these nominations.

THE anniversary meeting and annual dinner of the Royal Society will take place on Monday next—St. Andrew's Day.

THE session of the Society of Arts was commenced on Wednesday last by a most important address by the President, Sir F. Abel, on Appliances used in Mines. We shall give this on a subsequent occasion.

SIR JOSEPH HOOKER, we learn, retires, after a tenure of twenty years, from the Directorship of Kew Gardens on the 30th of the present month.

THE Savilian Professor of Geometry, J. J. Sylvester, M.A., Hon. D.C.L., proposes to deliver a public lecture on Saturday, December 12, at 4.45 p.m., in the Mathematical Lecture Room in the University Museum, Oxford, "On a General Theory of the Necessary Singularities of Curves of Unspecified Order." The lecture, although presupposing some elementary knowledge of modern algebra, will not go into details of calculation, but will have for its principal object to bring to light the existence of a new world of algebraical forms, co-ordinate in extent and parallel in character, genesis, and laws of association with those which occur in the theory of invariants.

WE hear with regret that there is a possibility of the *Zoological Record* being discontinued after the close of the next (the 21st) annual volume, unless additional support be received from those most intimately concerned in the welfare of this useful and (to zoologists) indispensable *résumé* of the work done in each year. It will be a standing disgrace to British, Colonial, and American zoologists, if they allow the *Record* to lapse on attaining its majority. Those who have worked with it cannot but acknowledge the aid it has afforded them; those who work without it run the risk of finding themselves anticipated. There are probably many local societies, public libraries, institutions, and private individuals that have not yet supported it, but should do so. The *Zoological Record* Association consists of members and subscribers. Members render themselves liable to the extent of 5*l.*, and on the exhaustion of this sum can withdraw or renew their membership. They receive the annual volume, and the average cost to them has at present amounted to about 24*s.* Subscribers pay annually 1*l.*, for which they receive the volume, and incur no further liability. All those who are interested in the continuance of our *Zoological Record*, and who are not already amongst its supporters, should lose no time in communicating with the Secretary of the *Zoological Record* Association, Mr. H. T. Stainton, F.R.S., Mountsfield, Lewisham, London, S.E.

THE Elizabeth Thompson Science Fund, which has been established by Mrs. Elizabeth Thompson, of Stamford, Connecticut, "for the advancement and prosecution of scientific research in its broadest sense," now amounts to $25,000. As the income is already available, the trustees desire to receive applications for appropriations in aid of scientific work. This endowment is not for the benefit of any one department of science, but it is the intention of the trustees to give the preference to those investigations, *not already otherwise provided for*, which have for their object the advancement of human knowledge, or the benefit of mankind in general, rather than to researches directed to the solution of questions of merely local importance. Applications for assistance from this fund should be accompanied by a full statement of the nature of the investigation, of the conditions under which it is to be prosecuted, and of the manner in which the appropriation asked for is to be expended. The applications should be forwarded to the Secretary of the Board of Trustees, Dr. C. S. Minot, 25, Mount Vernon Street, Boston, Mass., U.S.A. The first grant will probably be made early in January, 1886.

LA Société de Physique et d'Histoire naturelle de Genève offers a prize of 500 francs for the best unpublished monograph on a class or family of plants. The prize was founded by A. P. de Candolle. Manuscripts may be written in Latin, French, German (in Roman letters), English, or Italian, and should be sent in to the President of the Society before October 1, 1889, to the Athenæum, Geneva. Members of the Society are not permitted to compete, and the prize may be reduced, or not awarded at all, in the event of the essays being insufficient, or not conforming to these rules. The Society hope to be able to give the successful monograph a place in their *Transactions*, should that mode of publication be agreeable to the author.

TELEGRAMS from Madrid state that earthquake shocks have again occurred at Velez Malaga, on the coast of the province of Malaga. There appears also to be some seismic movement on the opposite African coast, producing landslips of considerable magnitude close to the Mediterranean, while the bed of the sea at the points affected is reported to have sensibly risen. There have also been sharp shocks of earthquake in Andalusia, especially at Alhama, which suffered so much last year.

DR. FOREL writes that the following shocks of earthquake have been observed in Western Switzerland:—November 15, 2h. 15m. a.m., at Sion, Gryon, Ollon, or the same region which was affected on September 26 last; November 18, 9h. 25m. p.m., Chevroux, south-east bank of Lake Neuchâtel; November 20, 5h. 45m. a.m., at Gondo, on the south face of the Simplon.

SEVERAL great earthquake waves from the Pacific were observed at San Francisco on November 19 between 1 and 8 o'clock p.m. at intervals of thirty-five minutes.

BRIGADE-SURGEON AITCHISON, the naturalist with the Afghan Boundary Commission, arrived in England on the 23rd inst. He brought his numerous collections with him as far as Batoum, and there shipped them on an English steamer for London. He has succeeded in obtaining a very fine specimen of a tiger from Turkestan, which, if it should reach England alive, will be unique of its kind, as no living specimen of this animal from those districts has as yet been brought to Europe.

CAPT. MANGIN, the inventor of the system of optical telegraphy as now practised in the French Army, has died suddenly from an attack of apoplexy at the early age of forty-five.

THE committee for erecting a statue in commemoration of the late Dr. Broca has opened a public competition for this monument.

THE French Minister of War has granted new credits to the Meudon aëronauts for the construction of a larger balloon. Workmen are enlarging the shed for building the apparatus.

M. MENIER, the well-known electrical engineer and contractor, has purchased a large property, rue de Chateaud'un (Paris), and is rebuilding it on a new system. He will sell electric light to all the lodgers in the house at a reasonable rate. It is the first time this speculation has ever been tried in Paris.

WE understand that the Science and Art Department have given their sanction to the exhibits from the Buckland Museum Collection being retained by the South Kensington Aquarium authorities until the close of the Indian and Colonial Exhibition next year. A better position for them could not be found, more especially as the casts of fish hung upon the walls are in *bon accord* with the living specimens in the tanks.

THE Norwegian Forest Association, started in 1881, is making very good progress. At present there are about 250 members. The Association's journal for the current year, embracing some 300 pages, contains a number of important papers by the most eminent Norwegian writers on the subject of forests and forest culture. A meeting for the discussion of important subjects takes place annually. The question of preserving the old and cultivating new forests appears to be coming more and more to the front in Scandinavia, where the Government has now established several schools with plantations for the cultivation of young plants. In Sweden the children of the rural Board-schools are often employed on fine days in planting out young trees. Thus during last summer some thousand acres have been planted in a single parish alone. Of late years private individuals too have done a great deal to retrieve the deforestation which has been going on by planting new trees. In one single parish in Norway, for instance, a proprietor has planted on waste land no less than a quarter of a million of spruce, fir, and larch trees, all obtained from the Government nursery. The price of the young plants is one farthing, and only 10 per cent. of the plants die. After thirty years each is valued at 7*d*. in the ground. These are of course valuations in a country where both labour and timber are cheap.

WE learn that Dr. J. G. Garson has just been elected a Corresponding Member of the Anthropological Society of Paris.

As a memorial to the late Sir Titus Salt, and in recognition of his benefactions to Saltaire, the Governors of the Salt Schools have decided to build a new Science and Art School, costing about 6000*l*. The building will be completely finished by May 15, on which day will be opened an important exhibition on the lines of the late International Inventions Exhibition. For this purpose the present buildings and a field of six acres will be utilised. The arrangement and supervision of the lighting and other electrical work have been intrusted to Messrs. Woodhouse and Rawson, of London.

IN the last number of the *Bulletin* of the American Geographical Society, Mr. Ernest Ingersoll publishes a paper on the manner in which the settlement of North America has affected its wild animals. He takes in succession the customary divisions of animal life—mammals, birds, reptiles, fishes, and the almost countless invertebrates, and shows how far these prevailed geographically in historical times, and how they have now either disappeared altogether, or been driven northwards into the Canadian forests, or, in the case of fish, away from the coasts. Mr. Ingersoll thus ranges over the whole animal kingdom, and in every department he has to record destruction—in many cases wanton and useless—and disappearance. It is a most instructive and interesting paper.

THE Sanitary Institute of Great Britain has just completed the preparation of a volume which will be of great interest to the statistical world, containing selections from the reports and writings of the late Dr. W. Farr. The selection of the papers and reports and the editing of this work have been undertaken by Mr. Noel A. Humphreys, of the Registrar-General's Office. The volume consists of 550 pages and is divided into six parts: (1) population, (2) marriage, (3) births, (4) deaths, (5) life tables, (6) miscellaneous. It has long been the source of much regret among students of vital statistics, and others practically interested in that branch of sanitary science, that from the form and manner of the publication of Dr. Farr's valuable papers on statistics they have not been generally available, being scattered over a long series of Blue-Books and other Reports. The object of the Institute in publishing the selection is to give those interested in the subject a ready means of studying the valuable writings and tables of that eminent statistician.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mrs. Berry; two Black-eared Marmosets (*Hapale penicillata*) from South-East Brazil, presented by Miss L. M. Graham; two Emus (*Dromæus novæ-hollandiæ*) from Australia, presented by Lord Northesk; an Emu (*Dromæus novæ-hollandiæ*) from Australia, presented by Mr. A. Garrett Smith; a Cuvier's Podargus (*Podargus cuvieri*) from Australia, presented by Mr. Cromwell Collins; a Tawny Owl (*Syrnium aluco*), British, presented by Mr. Phillips; an Anaconda (*Eunectes murinus*) from Demerara, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Robben Island Snake (*Coronella phocarum*), a Hoary Snake (*Coronella cana*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.

OUR ASTRONOMICAL COLUMN

THE FRENCH PHOTOGRAPHS OF THE TRANSIT OF VENUS.—The measurement of the 700 photographs obtained at the various French stations during the transit of Venus, 1882, is about to be commenced. An office has been organised for the purpose, the necessary credit has been granted, and a measuring instrument, belonging to the Meudon Observatory and lent by M. Janssen, has been supplied. This will be replaced in January next by a smaller one by the same makers, MM. Brunner, Frères. The measurements, it is expected, will be completed in fifteen months.

THE ABSORPTION-SPECTRUM OF OXYGEN.—M. Janssen, continuing at the Meudon Observatory his important and difficult researches on the spectra of the gaseous constituents of the terrestrial atmosphere, has recently given (*Comptes rendus*, vol. ci. No. 14) a brief notice of the results he has obtained. The spectrum of an intensely brilliant light is viewed through a tube 60 m. in length containing oxygen, the pressure of the gas being constantly increased up to a pressure of 27 atmospheres. With the increase of pressure, dark lines or groups of lines appear. The first to appear are those groups in the red, which M. Egoroff, who was the first to observe them, considered to be the A and B of the solar spectrum. With higher pressures, and a more brilliant source of light, lines are suspected between A and B and between B and C. Lastly, with the greatest pressures three dark bands appear; one near *a*, one near D, but more refrangible, and one in the blue. The solar spectrum does not show any similar bands, which, therefore, can scarcely be ascribed to oxygen in the state in which it exists in our atmosphere.

THE APPARENT ENLARGEMENT OF CELESTIAL OBJECTS NEAR THE HORIZON.—M. Paul Stroobant has recently devoted a considerable amount of care to examining the cause of this well-known phenomenon. His experiences lead him to reject the theories most commonly received, that the appearance is due either to comparison with terrestrial objects, or to the "flattened arch" shape ascribed to the celestial vault. Experiments made with pairs of electric sparks in a lofty hall, showed that if the two sparks overhead were 100 mm. apart, the pair on a level with the eye, and equally distant from the observer, needed only to be 81·5 mm. apart to seem separated to a similar extent. Comparisons of various pairs of stars gave a similar result, and the following formula was found to represent the apparent size, G, of a celestial object, at any given altitude, H, when the size on the horizon was taken as 100:—

$$G = 100 - 19 \sin H.$$

Beside this relation, depending evidently on some physiological effect connected with the position of the head, M. Stroobant found that an increase in the brightness of an object caused an apparent diminution in its size, and *vice versâ*. The great apparent size of the moon at rising was therefore, he considered, largely due to its comparative faintness when near the horizon.

NOVA ANDROMEDÆ AND ITS RELATION TO THE GREAT NEBULA.—There seems to be considerable difference of opinion as to whether the new star is to be regarded as having a real physical connection with the nebula, or as being connected with it in appearance only. M. Trouvelot (*Comptes rendus*, vol. ci. No. 17) ably pleads for the latter view. Comparing the present aspect of the nebula with the chart he made of it in 1874, he finds two new stars in the central district, one being the present *Nova*, the other a star of the 13th or 14th magnitude, which precedes it by about 20s. But he believes that the nebula itself has undergone no change during the appearance of the *Nova*, the impressions to the contrary being, he thinks, due to the superior light of the star having overpowered for a time the surrounding portions of the nebula; so that the arguments founded upon these supposed or apparent changes lose their force. The 1874 chart shows some 1283 little stars, which by their feebleness and crowding present the characteristic features of the Milky Way, which indeed appears to extend somewhat beyond the nebula; and these stars also appear to become less and less numerous the farther the observer travels from the Milky Way.

But none of the stars visible upon the nebula show diffused or ill-defined borders; so that they are probably neither in the nebula nor behind it, but before it, and forming part of the Milky Way. And as the two new stars alluded to are also well and clearly defined, he argues that they also are connected with the Milky Way, and not with the nebula, which he regards as lying behind it.

THE NICE OBSERVATORY.—The great objective of 30 inches diameter, intended for the Nice Observatory, and the glass for which was supplied by M. Feil, has just been completed by the Brothers Henry, and has been placed in the hands of M. Gautier, who is constructing the equatorial, which he hopes to finish by April next.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *NOVEMBER* 29 *TO DECEMBER* 5

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 29

Sun rises, 7h. 43m.; souths, 11h. 48m. 35·7s.; sets, 15h. 54m.; decl. on meridian, 21° 34′ S.: Sidereal Time at Sunset, 20h. 29m.

Moon (at Last Quarter) rises, 23h. 16m.*; souths, 6h. 9m.; sets, 12h. 49m.; decl. on meridian, 6° 58′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	9 45	13 20	16 55	25 47 S.
Venus	11 25	15 14	19 3	23 56 S.
Mars	23 22*	6 16	13 10	9 49 N.
Jupiter	1 31	7 36	13 41	0 16 N.
Saturn	17 49*	1 58	10 7	22 23 N.

* Indicates that the rising is that of the preceding day.

Occultations of Planet and Star by the Moon

M signifies maximum; *m* minimum.

The spectrum of R Andromedæ R.A. 0h. 17m. 58s., Decl. 37° 56′·4 N. deserves attention. The star is now approaching its maximum.

The following circular has been sent out from Lord Crawford's Observatory, Dun Echt:—"Considering the great uncertainty which envelopes the fate of Biela's comet, it seems desirable to call to mind that about midnight on the 27th inst. the earth will be in the path of the meteors seen to radiate from near γ Andromedæ on November 27, 1872. The comet's periodic time, and presumably that of the meteors being about 6·6 years, nearly two periods will have elapsed since the meteoric shower of 1872. If, therefore, the meteors are very widely distributed along the comet's orbit, there is a chance that they may again appear in considerable numbers this year. In 1892, and still more in 1905, there is a probability of a return of the display of 1872.

GEOGRAPHICAL NOTES

LIEUT. GREELY has been lecturing in Scotland on the Arctic Expedition of which he was the commander. At Dundee, on Monday night, having described the retreat from Discovery Harbour, Lady Franklin Bay, he went on to speak of the results of the Expedition, which could be done only in a general manner. The temperature observations, he remarked, were mainly important in determining the fact that Grinnell Land had the lowest mean temperature in the globe, about 4° F., or 20° C. below zero. This was in accordance with their expectations. The tidal observations, only roughly reduced by him at Conger, confirmed the work of 1875-76, but a large number of simultaneous readings at seven special stations in the Polar Sea, Robeson and Kennedy Channels, should enable tidal experts to determine quite accurately the shape and direction of the tidal wave, an important element in the theoretical determination of the configuration of lands and sea-bottom to the north. In Grinnell Land the discovery of coal not only at various points along the sea-coast, but at others in the interior, proved conclusively the changed climatic condition, as did the fossil forest found near Cape Baird in 81° 30′ N. Discoveries of Eskimo remains were of interest as showing the possible extent of this immigration of a new race into the Polar Basin. The Lieutenant next spoke of geographical discoveries. The furthest point seen by Beaumont was Cape Britannia, nearly 50 miles beyond the extreme point actually attained by that heroic officer. From Britannia Island Lieut. Lockwood and Sergeant Brainard pushed on 100 miles further, and passed a day and a half at Lockwood Island, the furthest point by land or sea ever attained by civilised man, in 83° 24′ N., 40° 46′ W. From an elevation of nearly 3000 feet it was evident that no land existed within a radius of sixty miles to the north or north-westward, but to the north-east the Greenland coast yet trended, ending to the eye at Cape Washington in 83° 35′ N. To Greenland was thus added 125 miles of new coast excluding the fiord lines, and from Cape May the mainland was carried a degree of latitude to the northward. In carrying Greenland 10° of longitude further to the eastward, Lieut. Lockwood left but 16° for his successors to fill in. The new land is composed of high precipitous promontories along the coast, and equally broken country inland, in which but three glaciers were seen, none discharging. It was evident that the inland ice-cap of Greenland stopped far to the southward of the 82nd parallel. In short, there existed from Robeson and Kennedy Channels, westward to Greely Fiord and the Polar Sea, a series of fertile valleys clothed with vegetation of luxuriant growth, whereon were large herds of musk oxen. He desired to say a few words as to his discoveries concerning the much-talked-of palæocrystic ice, especially the floebergs from 100 to 1000 feet thick. The opinion advanced by Sir G. Nares that this ice formed over the Arctic Ocean was not borne out by facts, and he could not commit himself to the judgment that this sea was for ever unnavigable, for they knew that a quantity of the ice changed from year to year, and little of it was seen by Lieut. Lockwood to the northward of Cape May. Dr. Moss was certainly correct as to the universality of stratification in this ancient ice, and he concurred in the opinion that its salinity was due to efflorescence and infiltration. There was no doubt in his mind that these floes were simply detachments of slowly-moving glacial ice-caps from an ice-covered land in the neighbourhood of the Pole. Lieut. Lockwood found small floebergs, perhaps 100 to 200 feet thick, detached from the adjacent ice-caps. In Kane Sea he visited a floeberg a third of a mile wide, a quarter of a mile long, and from a fifth to a sixth of a mile thick. The proof as to its terrestrial origin no one would dispute; on its surface were two valleys about 30 feet deep, along which were the medial moraines of the glacier—fully 100 large stones polished and worn smooth in places by the parent ice. He thought it doubtful whether such an ice-cap increased by more than three or four inches yearly, so that from 3000 to 4000 years might easily have elapsed since the incipient birth of the berg in question. Lieut. Greely advocated future Arctic exploration in the direction of Franz Josef Land.

MR. GAMEL, at whose sole expense the late expedition to the Kara Sea, under Lieut. Hovgaard, was undertaken, intends, provided his enterprise be seconded by the Government, to send his steamer *Dijmphna* next summer on an expedition, under an officer of the Danish Royal Navy, to the east coast of Greenland, to explore and lay down the coast-line between 66°·08, the farthest northward point attained by Capt. Holms's expedition, and 70°.

ACCORDING to the *Gazette Géographique*, M. Moller, who was recently charged with a mission of botanical investigation to the Island of St. Thomas, has returned to Lisbon. He has brought with him a large number of interesting specimens, not only of the botany, but also of the geology, of the island. These have been placed for investigation in the hands of M. Henriques, the Professor of Botany of the Coimbra University. M. Moller has also made some important additions to and corrections in the map of St. Thomas recently published. He has proved that the highest mountain in the island is the Peak of St. Thomas, and that its height is 2142 metres.

AN officer of the French Navy, Commander Réveillère, has succeeded in a daring attempt which he made recently to ascend the rapids of the Meikong, beyond Samboc, in a steamer. Samboc is the chief Cambodian town on the river, and at one time it was thought impossible for a steamer even to reach that point. A short distance above the town commences a series of rapids, which last for about forty miles, and which in parts appear as formidable obstacles to navigation as the cataracts on the Nile. Commander Réveillère, however, succeeded in overcoming them, but only after such exertion and danger as make it clear that in their present state they present an insuperable barrier to navigation for commercial purposes. He proposes a thorough hydrographic study of this section of the river at low water, and he is convinced that the famous barrier will turn out to be merely a mass of trees which has got permanently fixed there and is maintained by annual additions, but which can be removed without difficulty by means of explosives. Beyond the rapids is the town of Stung-Treng, where the greater part of the commerce of the Laos reaches the river, and hence the advantage of a navigable passage. Commander Réveillère concludes his account of his feat by recommending "a serious hydrographic campaign in the rapids of the Meikong, and in the lower Laos." The Meikong is one of the greatest of the great rivers of Asia; it was first thoroughly explored fifteen years ago by a mission under Lagrée and Garnier, which came to the conclusion that this magnificent water-way was useless for trade purposes on account of its rapids.

LIEUT. ALLEN has lately returned to San Francisco from a successful exploration of Alaska, undertaken by direction of the United States Government. He left Sitka in February, going to the mouth of the Copper River, which he ascended as far as the great mountain range of Alaska. He crossed the mountains with snow-shoes, coming to the sources of the Tennah, which river he followed for 800 miles to its junction with the Takon, and he descended this latter river to its mouth, a journey of between 400 and 500 miles. From the mouth of the Takon he went to Fort Michael, on Behring's Straits, whence he came home.

THE proposal that the Netherlands Government should make a grant to the Dutch Geographical Society towards the expenses of the projected scientific expedition for the exploration of the half of New Guinea belonging to Holland has been rejected by the Second Chamber by a large majority, there being forty-nine votes against the motion to twenty-one in favour of it. In the debate most of the speakers expressed their conviction of the desirability of the expedition maintaining the character of a purely private enterprise.

A NEW edition of Dr. Hunter's "Indian Gazetteer of India" in twelve volumes is in the press. Several of the volumes will be published in the course of the next few weeks.

THE November number of the Austrian *Monatsschrift für den Orient* contains a long communication from Dr. Lenz, from Ango-Ango, with reference to his expedition to the Congo. It deals mainly with the superficial aspects of the various settlements on the West Coast of Africa, of the trade there and its future prospects, and especially with the prospects of Austrian trade.

UNDER the title, "La Corée avant les Traités," M. Jametel, a French writer on the Far East, has published, in a *brochure* of about eighty pages, four articles which he contributed to recent numbers of *La Revue de Géographie*. He describes the voyage from Nagasaki to Fusan, a Corean port then only opened to Japanese trade, and gives a sketch of the history of the peninsula from early times; finally he describes the Japanese settlement at Fusan and the neighbouring Corean town of Toraifu, and adds a few words about the Island of Quelpaest. The account is very lively and amusing, but it can hardly be said to add much to our geographical knowledge of Corea, small as that was before the treaties.

CHLOROPHYLL[1]

ALL who are accustomed to observe vegetation must have been struck with the great variety of shades of green which the foliage of different plants presents. Without pretending to generalise further, it may be stated that, at any rate so far as our common agricultural plants are concerned, they show somewhat characteristic shades of colour, according to the *Natural Order* to which they belong—the Leguminosæ differing from the Gramineæ, the Cruciferæ, the Chenopodiaceæ, and so on. But the same description of plant will exhibit very characteristic differences, not only at different stages of growth, but at the same stage in different conditions of luxuriance, as affected by the external conditions of soil, season, manuring, &c., but especially under the influence of different conditions as to manuring.

The Rothamsted field experiments have afforded ample opportunity for observations of this kind; and it has been quite evident that, in a series of comparable experiments with the same crop, depth of green colour by no means necessarily implied a finally greater amount of carbon assimilation; whilst we have long ago experimentally proved that the deeper colour was associated with relatively high percentage of nitrogen in the dry or solid substance of the herbage; and this obviously means a lower relation of carbon to nitrogen.

Mentioning these facts to Dr. W. J. Russell, who has devoted so much attention to the subject of chlorophyll, he kindly undertook to make comparative determinations of the amounts of chlorophyll in parallel specimens, in which we were to determine the percentages of dry matter and of nitrogen. Accordingly in June, 1882, during the period of active vegation, Dr. Russell spent a day at Rothamsted for the purpose of collecting appropriate samples, which were taken from several differently-manured plots of meadow-grass, wheat, barley, and potatoes, respectively.

The following table gives the results of some of these experiments; namely, the percentages of nitrogen, and the relative amounts of chlorophyll, in the separated gramineous and the separated leguminous plants in the mixed herbage of grass-land; in specimens of wheat grown by a purely nitrogenous manure, and by the same nitrogenous manure with a full mineral manure in addition; and in specimens of barley grown by a purely nitrogenous manure, and by a mixture of the same nitrogenous manure and mineral manure in addition. It is to be borne in mind that the specimens were collected while the plants were still quite green and actively growing. It should be further explained that the amounts of chlorophyll recorded are, as stated in the table, relative and not actual; that is to say, the figures show the relative amounts for the individual members of each pair of experiments, and not the comparative amounts as between one set of experiments and another.

It will be seen in the first place that the separated leguminous herbage of hay contained a much higher percentage of nitrogen in its dry substance than the separated gramineous herbage; and that, with the much higher percentage of nitrogen in the leguminous herbage, there was also a much higher proportion of chlorophyll. Under comparable conditions, however, the Leguminosæ eventually maintain a much higher relation of nitrogen to carbon than the Gramineæ; in other words, in their

[1] "Note on some Conditions of the Development, and of the Activity, of Chlorophyll." By Prof. J. H. Gilbert, LL.D., F.R.S. Read in Section B at the meeting of the British Association at Aberdeen, September, 1885. (Abstract.)

case carbon is not assimilated in so large a proportion to the nitrogen taken up.

Next, it is to be observed that the wheat-plants manured with ammonium-salts alone show a much higher percentage of nitrogen than those manured with the same amount of ammonium-salts but with mineral manure in addition. The high proportion of chlorophyll again goes with the high nitrogen percentage; but the last column of the table shows that, with the ammonium-salts without mineral manure, with the high percentage of nitrogen, and the high proportion of chlorophyll, in the dry substance of the green produce, there is eventually a very much less assimilation of carbon. The result is exactly similar in the case of barley; the plants manured with ammonium-salts alone showing the higher percentage of nitrogen, and the higher proportion of chlorophyll, but eventually a much lower assimilation of carbon.

It is evident that the chlorophyll formation has a close connection with the amount of nitrogen assimilated, but that the carbon assimilation is not in proportion to the chlorophyll formed, if there be a relative deficiency of the necessary mineral constituents available. No doubt there has been as much, or more, of both nitrogen assimilated and chlorophyll formed, over a given area, where the mineral as well as the nitrogenous manure had been applied, the lower proportion of both in the dry matter being due to the greater assimilation of carbon, and consequently greater formation of non-nitrogenous substances.

It is of interest to observe that these results of experiments in the field are perfectly consistent with those obtained by vegetable physiologists in the laboratory; they having found that the presence of certain mineral or ash constituents, and especially that of potassium, is essential for the assimilation of carbon, no starch being formed in the grains of chlorophyll without the aid of that substance. Sachs says:—"Potassium is as essential for the assimilating activity of chlorophyll as iron for its production."

Relation between Nitrogen Accumulation, Chlorophyll Formation, and Carbon Assimilation.

The figures in parentheses represent determinations in the not fully dried substance.

	Nitrogen per cent. in dry substance.	Relative amounts of Chlorophyll.	Carbon assimilated per acre per annum.

CARTOGRAPHICAL WORK IN RUSSIA IN 1884[1]

THE chief surveys in European Russia are directed towards mapping South Finland, the western frontier on the Duna and Dnieper, and the Government of Taurida. The surveys are made on a scale of 1750 feet to the inch, and the inequalities of soil are represented by horizontal lines received from accurate levellings. Since 1870 about 44,000 square miles have been thus mapped, and, in 1884, 6850 square miles were added to the above, the newly-annexed part of Bessarabia included. The geodetical triangulation for this survey was continued in Poland and Grodno. The work for an orographical map of Russia, which must be based on accurate levellings, has been busily continued since 1881, as also telegraphic determinations of longitudes in Poland.

[1] *Izvestia* of the Russian Geographical Society, September, 1885.

Instead of the former map of West and Middle Russia, on 150 sheets, on the scale of 3 versts (2 miles) to an inch, the Topographical Department is now preparing a new map on a larger scale (2 versts to an inch), which will be printed on a new method, by helio-engraving, with level-lines in a separate colour. Many preliminary essays having been made, this method has been definitively adopted. The map of Russia (10 versts to an inch) has been completely revised by General Strelbitzky; and the map of the Caucasus, on the same scale, was completed in 1884. The northern and north-eastern sheets of the map of European Russia will be completely revised in accordance with new surveys.

The map of the Asiatic dominions of the Empire, with the neighbouring regions (100 versts to an inch), is completed, and is printed in colours. That of the eastern part of the Balkan peninsula is prepared on two different scales (5 and 3 versts to the inch), and on both maps the inequalities of the soil are represented by horizontal lines. The middle parts, including the Balkan ridge, were ready to print. Helio-engraving had also been resorted to, but it required considerable retouching by the engraver.

Leaving aside the purely military maps of Middle Europe and the statistical maps of the St. Petersburg military district, the following maps, published in 1884, are especially worthy of notice:—The region of the Cossacks of the Ural (10 versts to an inch); the Island of Sakhalin (40 versts); North-Western Mongolia (50 versts), including all the rich materials collected by the expeditions of MM. Potanin, Rafailoff, Orloff, Prjevalsky, Pevtsoff, and several others; Afghanistan (50 versts), according to the surveys and information of M. Lessar; the south-western Turkoman region, by the same (20 versts); the surveys of M. Kosyakoff in Karategin and Darvaz (15 versts); the survey from Staro-Tsurukhaitu to Aigun, on the Amur (25 versts); a map of China proper, by M. Matusovsky (100 versts); the plans of Odessa, Nikolaieff, Ekaterinoslav, Bendery, and Elizabethgrad, as also of Plevna and Lovtcha; the neighbourhoods of Kazan and of Novogeorgievsk, and many others.

On the Caucasus, as soon as the triangulation of the region was terminated some fifteen years since, a series of surveys, on scales of 1400, 1750, and 3500 feet to an inch, were undertaken. Large parts of Transcaucasia were thus mapped. Since 1881 the work has been prosecuted in the central parts of the great Caucasus ridge, in Daghestan, and in the Transcaspian region; about 30,000 square miles were thus surveyed. In 1884 the chief surveys were made in the teritory of Merv, along the Murghab; and on the routes between Kizil-arvat, Petro-alexandrovsk, Khiva, and Merv. The drawing and engraving of the great map of the Caucasus with the neighbouring parts of Persia and Turkey, as also of that of the Transcaspian region, both on a scale of 5 versts to the inch, have been prosecuted.

In Turkestan the chief attention has been directed towards the survey of the former khanate of Kokan, now the province of Ferghana, the work meeting with great difficulties owing to the hilly character of the region and its unhealthy climate. Reconnoitring has been prosecuted in the vassal khanates of Bokhara, west of the Pamir, by a topographer who accompanied Dr. Regel.

The mapping of the town of Tashkend, which covers as much as thirty-five square miles, and where trigonometrical measurements meet with great difficulties on account of refraction and the want of wood for the triangulation-pyramids, a system known under the name of *Polygonale Züge*, and which has been greatly extended of late in Germany, has been resorted to. The horizontal angles were measured by a little universal instrument, and the distances by a ribbon, with the help of the eclimetre. The results obtained were very satisfactory. Several new sheets of the 10 versts map were printed, as also a map of the neighbourhood of Tashkend.

In the Omsk military district, detailed surveys, based on a geodetical net, have been prosecuted since 1870 to the south-west of the Irtish River, between its sources and Pavlodar. In 1883 and 1884 large spaces in the region between Omsk, Pavlodar, Petropaulovsk, and Kokchetav were mapped, and a series of latitudes and longitudes were determined.

In Eastern Siberia the Government of Irkutsk is now surveyed on a scale of one verst to the inch, the trigonometrical net having been completed in 1882. The upper parts of the Vition and Barguzin were reconnoitred, and the trigonometrical net extended in Southern Transbaikalia. On the Pacific coast, the region east of the Suifun River, and on the Chinese frontier, has been surveyed.

The following maps, published by the Military Commissariat, deserves also a short notice:—A map of European Russia, showing for each government the surplus, or the want of, rye raised within the government, as also its price, which map leads to very interesting geographical conclusions; a map showing the average crops proportionately to the population; and a map of the sheep-breeding in Russia.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The first award of the Smith's Prizes under the new regulations has been made. They are now given to the Bachelors of Arts who send in the best essays on any subject in Mathematics or Natural Philosophy before the end of the Lent Term in the second year after each Mathematical Tripos. Thus the competitors this year took their degree in the Mathematical Tripos of 1883–84. The Smith's Prizes this year are awarded to two essays declared equal in merit, viz. that of Mr. H. E. G. Gallop, Fellow of Trinity College, Second Wrangler in 1883, 1st Division in Part III., 1884, subject, "The Distribution of Electricity on the Circular Disk and Spherical Bowl"; and that of Mr. R. Lachlan, Fellow of Trinity College, 3rd Wrangler, 1883, 1st Division in Part III., 1884, subject "Systems of Circles." It is further announced that the essay by Mr. C. Chree, Fellow of King's College, on "Elastic Solids," and that of Mr. A. N. Whitehead, Fellow of Trinity College, on the "General Equations of Hydrodynamics," deserved honourable mention.

The Special Board for Medicine have reported in favour of the immediate appointment of a Demonstrator of Pathology, with a stipend of 100*l*. a year, to assist Prof. Roy, who now gives systematic lectures three times a week, conducts a practical course for two hours twice a week, and undertakes the autopsies at Addenbrooke's Hospital.

The Chemical Laboratory Syndicate have recommended the acceptance of Messrs. Bull, Sons, and Co.'s tender (Southampton) for 19,300*l*.

The following appointments to Syndicates and Boards have been made:—

Botanic Garden: Messrs. A. H. Cooke and W. Gardiner.
University Library: Prof. A. Macalister.
Museums and Lecture Rooms: Messrs. E. H. Morgan and R. T. Caldwell.
Local Examinations: Mr. J. W. Hicks.
Observatory: Dr. Routh and Mr. J. Larmor.
University Press: Prof. A. Macalister.
State Medicine: Prof. Latham and Dr. D. McAlister.
Mathematics: Dr. Routh.
Physics and Chemistry: Mr. C. Trotter.
Biology and Geology: Mr. W. Gardiner.

Great opposition has been given to the new proposals as to the additional subjects of the Previous Examination required of candidates for honours. As Mr. Oscar Browning said, "dealing with this subject seemed to cast an evil influence over every one who takes it in hand." The fact is the University, containing strong elements attached to and connected with the Public School system, refuses to boldly grasp the nettle and introduce English, Modern Languages, or Physical Science into its schemes for the Ordinary Preliminary Examination, and finds itself consequently in endless difficulties whenever it touches the question.

IN addition to the practical instruction in Biology (Zoology and Botany), in preparation for the Preliminary Scientific and B.Sc. Examinations at the University of London, which we have already announced as being given at Bedford (Ladies') College, York Place, Baker Street, we are informed that a class in Geology and Physical Geography has now been formed, in accordance with the requirements of the University, and that it will be conducted by Miss Mary Forster.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, November 5.—Dr. Hugo Müller, F.R.S., President, in the chair.—Mr. Leonard de Koningh was admitted a Fellow of the Society.—The following papers were read:—The influence of silicon on the properties of cast-iron, part 2, by Thomas Turner, Assoc. R.S.M.—Modifications of double sulphates, by Spencer Umfreville Pickering, M.A.—The relation of diazobenzene-anilide to amidoazobenzene, by R. J. Friswell and A. Green.—An examination of the phenol constituents of blast-furnace tar obtained by the Alexander and McCosh process at the Gartsherrie Iron Works, part 1, by Watson Smith, J. F. H. Coutts, and H. E. Brothers.—The decomposition of potassium chlorate by heat, by Frank L. Teed, F.C.S. Note on the refractive power of metacinname (metastyrole), by H. G. Madan, M.A., F.C.S.

Zoological Society, November 17.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary exhibited to the meeting two curious Millipedes, believed to be *Spirostreptus annulipes*, which had been sent home from the Cape by Mr. Fisk for the Insect House.—An extract was read from a letter addressed to the Secretary by Major S. W. Yerbury, respecting the exact locality of a Chameleon (*Chamæleon calcarifer*) presented to the Society by that gentleman in June, 1885. Major Yerbury had obtained this specimen near Aden.—Mr. Sclater exhibited and made remarks upon two Newts (*Molge vittata*) transmitted to the Society by Dr. E. B. Dickson, of Constantinople, C.M.Z.S., by whom they had been obtained from Brussa, Asia Minor.—Mr. H. E. Dresser exhibited and made remarks on a female specimen of the Kildeer Plover (*Ægialitis vocifera*), killed, in January, 1885, by Mr. Jenkinson on the Scilly Isles; and a young female Desert-Chat (*Saxicola deserti*) obtained near Spurn Head, Lincolnshire, in October, 1885.—Prof. F. Jeffrey Bell exhibited and gave an account of a specimen of a species of *Balanoglossus* obtained by Mr. Spencer at Herm, Channel Islands, being the first recorded instance of the occurrence of this Hemichordate in any part of the British seas.—Mr. F. E. Beddard read the first of a proposed series of notes on the visceral anatomy of birds. The present paper treated of the so-called omentum of birds and its homologies. It was pointed out that this structure, present in many birds, but apparently absent, or only present in rudiment, in a few others, was represented by a structure having similar relations in the Crocodile, but in no other reptile.—Mr. Oldfield Thomas read a description of *Heterocephalus phillipsi*, an extremely remarkable burrowing Rodent from Somali-land, belonging to a genus of which the only other known species was based upon a single specimen obtained by Rüppell's collector in Schoa. Mr. Thomas considered the affinities of this Rodent to be with *Georychus* and *Bathyergus*.—Mr. Sclater read a paper containing a description of an apparently new species of Tanager of the genus *Calliste*, based on a specimen formerly in the Gould Collection, now in the British Museum. Mr. Sclater proposed to dedicate this bird to its former owner as *Calliste gouldi*.—Mr. Boulenger gave the description of a new frog from Perak, Malacca, which he proposed to name *Megalophrys longipes*.

Physical Society, November 14.—Prof. Guthrie, President, in the chair.—Mr. G. M. Whipple described and demonstrated experimentally the process of testing thermometers at and near the melting-point of mercury, as carried on at Kew. About 20 lbs. of mercury are poured into a wooden bowl and frozen by carbonic-acid-snow and ether; the mercury is stirred with a wooden stirrer, and the snow is added till the experimenter feels, by the resistance to stirring, that the mercury is freezing. The stirring is continued for some time, which causes the mercury to become granular instead of a solid mass. The thermometers are then inserted, together with a standard, and compared. About 100 mercury or 40 spirit thermometers can be thus examined in half an hour, using about 200 gallons of carbonic acid gas compressed sufficiently to form the snow. The bowl, ether, and mercury are cooled first to $-10°$ C. by an ordinary freezing-mixture. The average correction at the melting-point of mercury is now less than 1° F.; when the process was introduced in 1872 it amounted to 5°, but has steadily decreased.—On the electromotive force of certain tin cells, by Mr. E. J. Herroun. Mr. Herroun has examined the electromotive forces of cells in which tin in a solution of its salts was opposed to copper, cadmium, and zinc in solutions of their corresponding salts, the solutions being of equal molecular strengths. The salts used were sulphates, chlorides, and iodides, and the cells were of the ordinary "Daniel" form, with a porous vessel. To prevent the formation of basic salts it was necessary to add a little free acid to the solution of the tin salt, and, to counterbalance the influence of this acid upon the E.M.F. as far as possible, an equal proportion of free acid was added to the other solution. Prof. G. Minchin pointed out the importance of performing these and similar experiments upon tin in the dark, as, by allowing light to fall upon the tin plate, a considerable photo-electric effect would be obtained. Prof. Fleming insisted upon the great importance of temperature corrections in all experiments upon two-fluid cells.—On the law of the electro-magnet and the law of the dynamo, by Prof. S. P. Thompson. It cannot be said up to now that any particular law has been generally accepted, giving the relation between the current in the coils of an electro-magnet and the magnetism induced by it in the core. Many empirical formulæ have been given, most of which are entirely wrong. One, however, recently enunciated by Fröhlich, gives a relation which agrees very closely with observed values. This formula is—

$$m = \frac{i}{a + bi},$$

where m is the magnetic moment of the core, i the current, and a and b constants depending upon the geometrical form of the magnet, and the nature and previous history of the iron core. Fröhlich obtained this relation by experimenting with a series-dynamo. It is purely empirical, but since it agrees so well with the facts as to give values for the magnetism of the core agreeing almost within experimental error with those observed, there is great probability of some law being at its base. And this law Prof. Thompson believes to be one that was stated years ago by Lamont:—"The magnetic permeability varies with the quantity of magnetism the iron is capable of taking up." This may be expressed by the formula—

$$\frac{dm}{di} = k(M - m.)$$

Integrating which and expanding e^{-ki} in powers of i—

$$m = Mki\left\{1 - \frac{ki}{2} + \frac{k^2 i^2}{6} \ . \ . \ . \right\}.$$

Expanding Fröhlich's equation, in powers of i, we get—

$$m = \frac{i}{a}\left\{1 - \frac{bi}{a} + \frac{b^2 i^2}{a^2} - \quad . \right\}.$$

If ki is not great these expressions will coincide in form very closely, and the results lead Prof. Thompson to accept Lamont's expression as being that of a real physical law. Prof. Perry suggested that Lamont's law gave good results from its being an approximation to Weber's theory of induced magnetism, but Prof. Thompson maintained that it represented observed facts better than that theory, which, as developed by Maxwell, shows a decided discontinuity in the process of magnetisation not actually observed. Prof. Fleming remarked upon the similarity of Fröhlich's expression to that for the current through a voltameter; the part $a + bi$ corresponding to the apparent resistance, which may be considered in this case as the resistance to magnetisation of the core-air circuit, and which, like that of the voltameter, varies with the current.

Geological Society, November 4.—Prof. T. G. Bonney, F.R.S., President, in the chair.—Dr. A. G. Nathorst, of Stockholm, was elected a Foreign Correspondent of the Society.—The following communications were read:—On the premaxillaries and scalpriform teeth of a large extinct wombat (*Phascolomys curvirostris*, Ow.), by Sir Richard Owen, K.C.B., F.R.S. The specimen described in this paper is a cast from a fossil discovered in a late exploration of the Wellington bone-caves, and sent to the author with some other casts from the same collection by the authorities of the Australian Museum, Sydney, New South Wales. The fragments in question consist of the premaxillary bones, containing a pair of scalpriform incisors, 160 mm. (6½ inches) long, measured along the outer curve. The teeth and the fragments of bone in which they are implanted were described in detail, and referred to the wombat family. The animal to which they belonged must have been somewhat larger than *Phascolomys medius*, Owen, but less than the type of the sub-genus *Phascolomys*. The specific name is suggested by the chief characters that distinguish the present form from any hitherto known, recent or extinct.—On the structure and classificatory position of some Madreporaria from the secondary strata of England and South Wales, by Prof. P. Martin Duncan, F.R.S. This paper consisted chiefly of a criticism of the conclusions arrived at by Mr. R. F. Tomes in various papers communicated to the Society.—On the *Astrocœniæ* of the Sutton Stone of the Infra-Lias of South Wales, by Prof. P. Martin Duncan, F.R.S.

Anthropological Institute, November 10.—Mr. F. Galton, F.R.S., President, in the chair.—The following elections were announced:—Prince Roland Bonaparte, Hon. Member; Dr. A. Asher, Dr. Alexander Bain, and Messrs. C. F. Clarke, J. W. Crombie, T. H. Edwards, P. Norman, and E. Tregear, as Ordinary Members.—This being the first meeting of the Session, the President made some opening remarks, in the course of which he congratulated the Institute upon the obvious increase of public interest in the science of man. Besides the gratifying facts that more new members are joining the Institute and that the corresponding Section of the British Association was popular, there are such evidences as that the authorities of Trinity College, Cambridge, have extended the tenure of one of their Fellowships to enable its holder to pursue his anthropological studies, and that at the meeting of the British Association at Aberdeen it was the Rector of the University, Dr. Bain, who contributed one of the most thoughtful of the anthropological memoirs. Mr. Galton proceeded to insist upon the political value of anthropology as the science that best qualifies us to sympathise with other races and to regard them as kinsmen rather than as aliens.—A paper containing a short account of some experiments in testing the character of school children as observers, was read by Mrs. Bryant. In these experiments an attempt was made to read signs of character in an observer from the manner in which he makes an observation and describes it as made. From the written description of (1) a room, (2) a picture, which the children experimented upon were first shown and then required to describe, a rough diagnosis of their character as observers can be made, and hence some idea of their character generally is obtained, which, though very deficient in precision and still more deficient in certainty, may have, nevertheless, a real practical value for educational and other purposes. In the experiments made the most interesting points noticed were:—(1) great variety in the proportions existing between the sensational and intellectual factors of perception; (2) the occasional prevalence of the tendency to substitute feeling for thinking, which is a very characteristic feature of general character where it exists; (3) varieties in degree and kind of orderliness; (4) differences in the degree of colour-interest, as also of interest in form and number; (5) great variety in degree and kind of imaginative play, as shown in the efforts of constructive explanation required to describe a picture.—Mr. Joseph Jacobs then read a paper entitled "A Comparative Estimate of Jewish Ability." In it he applied the same method to Jews and Scotchmen as Mr. Galton had applied to Englishmen in his "Hereditary Genius," with results favourable to the two former races in the order mentioned. The subjects in which Jews seemed to show superior ability were philology, music, metaphysics, and finance.

Royal Meteorological Society, November 18.—Mr. R. H. Scott, F.R.S., President, in the chair.—Messrs. T. R. H. Clunn, R. S. Davies, B.A., H. C. Fox, M.R.C.S., W. E. Jackson, J. Richardson, M.Inst.C.E., F.G.S., A. L. Rotch, and C. Todd, C.M.G., were elected Fellows of the Society.—The following papers were read:—The Helm wind of August 19, 1885, by William Marriott, F.R.Met.Soc. This wind is peculiar to the Cross Fell range, Cumberland, and is quite local, but very destructive. The chief features of the phenomenon are the following:—On certain occasions when the wind is from some easterly point, the helm suddenly forms. At first a heavy bank of cloud rests along the Cross Fell range, at times reaching some distance down the western slopes, and at others hovering above the summit; then at a distance of one or two miles from the foot of the Fell there appears a roll of cloud suspended in mid-air and parallel with the helm cloud: this is the helm bar. A cold wind rushes down the sides of the Fell and blows violently till it reaches a spot nearly underneath the helm bar, where it suddenly ceases. The space between the helm cloud and the bar is usually quite clear, blue sky being visible. At times, however, small portions of thin vaporous clouds are seen travelling from the helm cloud to the bar. The bar does not appear to extend further west than the River Eden. The author visited the district in August last, and was fortunate enough to witness a slight helm. He gives a detailed account of what he experienced, and also his observations on the temperature of the air at the summit and base of Cross Fell, the direction and force of the wind, the movement of the clouds, &c.—The typhoon origin of the weather over the British Isles during the second half of October, 1882, by Henry Harries. The author shows, by means of daily charts, that a typhoon which originated near the Philippine Islands on September 27 passed over Japan and the Aleutian Archipelago, entering the United States on October 10. Crossing the Rocky Mountain range, it proceeded through the Northern States and Canada to Labrador and Davis Strait. In the Atlantic it was joined on the 18th by another disturbance which had come up from the Atlantic tropics, the junction of the two being followed by a cessation of progressive movement from the 19th to the 25th. During this period the severe gale which passed along our southern counties on the morning of the 24th was formed, its sudden arrival upsetting the Meteorological Office forecasts of the previous night. Observations are quoted showing that it would have been impossible for the Department to have been aware of its existence before about 3 a.m. of the 24th. Following in the wake of this storm the parent cyclone reached the French coast on the 27th, its advent being marked, as in Japan and America, by violent gales and extensive floods over the whole of Western and Central Europe and Algeria. The village of Grindelwald was destroyed, and in the Austrian Tyrol the damage caused by floods reached at least two millions sterling. Passing through France and the Netherlands the disturbance showed signs of exhaustion, and on November 1, in the Baltic, it quietly dispersed, after accomplishing a journey of over 16,000 miles in thirty-six days. This is the first storm which has been followed day by day from the Pacific to Europe.—Notes as to the principle and working of Jordan's photographic sunshine-recorder, by J. B. Jordan and F. Gaster, F.R.Met.Soc. This instrument consists of a cylindrical dark chamber, on the inside of which is placed a prepared slip of photographic paper. The direct ray of sunlight being admitted into this chamber by small apertures in the side, is received on the sensitised paper, and, travelling over it by reason of the earth's rotation, leaves a distinct trace of chemical action whenever the light is of sufficient intensity to show a definite shadow on a sun-dial. The cylinder is mounted on a stand with adjustments for latitude, &c. The record is fixed by simply immersing it in water for a few minutes. As this instrument records the actinic or chemical rays, it usually shows more sunshine than is obtained by the ordinary "burning" sunshine-recorder.

EDINBURGH

Mathematical Society, November 13.—Mr. George Thom, Vice-President, in the chair.—Sir William Thomson communicated a theorem in determinants, which was read by Dr. Muir. Mr. J. S. Mackay gave an account of the ancient methods for the duplication of the cube.—Mr. William Harvey contributed some geometrical notes.—Mr. A. J. G. Barclay read a paper on physical science in schools.—The following office-bearers were elected:—President: Dr. R. M. Ferguson; Vice-President: Mr. George Thom; Secretary: Mr. A. Y. Fraser; Treasurer: Mr. John Alison; Committee: Messrs. R. E. Allardice, A. J. G. Barclay, W. T. Macdonald, J. S. Mackay, Dr. Thomas Muir, Mr. William Peddie.

PARIS

Academy of Sciences, November 16.—M. Jurien de la Gravière in the chair.—Researches tending to show that the trigemini nerves contain, from the first, vaso-dilatator fibres, by M. Vulpian.—Obituary notice of the late W. B. Carpenter, Corresponding Member for the Section of Zoology, by M. A. Milne-Edwards.—Treatment of the vine by a mixture of lime and sulphate of copper: determination of the distribution of the copper on the plant, and its persistence in the fruit and must, by MM. Millardet and Gayon. From these researches it appears that most of the copper remains deposited on the leaves, the must containing extremely small quantities, and the wine only doubtful traces, or at most 0·1 gramme in 1000 litres.—Letter accompanying the presentation of a new edition of Ptolemy's "Optics," by M. Gilbert Govi.—On the irregular integrals of linear equations, by M. H. Poincaré.—Dynamic effects produced by the passage of locomotive and carriage wheels at the junction of the rails, by M. A. Considère. It is shown that these effects constitute a new and important element in estimating the wear and tear of traffic on the metals of railways. Several experiments show that they are much more serious at the points of contact of the rails than had hitherto been supposed.—On the tension of saturated vapours, by M. E. Sarrau.—Theory of refrigerating mixtures, by M. A. Potier.—Theory of the flow of gases: adiabatic lines, by M. Marcellin Langlois.—On the theory of the receptor electro-magnetic telephone, by M. E. Mercadier.—Description of a new spectroscopic optometer, by M. Ch. V. Zenger. Besides its use in spectroscopic studies, this ingenious little instrument is expected to render great services to physiologists in determining the defective achromatism of the human eye and its variations with age.—Spectroscopic study of the flames of blast furnaces and of the Bessemer process, by M. Ch. V. Zenger.—On the numerical laws of the chemical equilibria, by M. H. Le Chatelier.—Fixation of free atmospheric nitrogen in cultivated ground, by M. H. Joulie.—Note on the physiological action of safranine, and of the crystallised sulfo de fuchsine used in colouring wines, by MM. P. Cazeneuve and R. Lépine. From various experiments made on dogs, pigs, and human subjects, the authors conclude that the fuchsine is a perfectly harmless substance without physiological or therapeutic interest, whereas safranine gives rises to serious toxic phenomena when injected into the veins in a solution of salt water containing 7 per cent. of this substance.—Note on the zymotic properties of charbon and some other kinds of virus, by M. S. Arloing.—Researches on the comparative anatomy of the chord of the tympanum in birds, by M. L. Magnien.—Note on the nerve centres of the cephalopods, by M. Vialleton.—Influence of the number of individuals in the same vessel, and of the form of the vessel on the development of the larvæ of the frog (*Rana esculenta*), by M. E. Yung. The author finds that the rapidity of development is in inverse ratio to the number of tadpoles in the vase, although the supply of food may be superabundant; also that the development is the more rapid the larger the diameter (and consequently of the surface exposed to the air) of the vessels.—Note on the respiration of leaves in the dark, by MM. Dehérain and Maquenne.—On the variations presented by the composition of the gases in the foliage of plants growing in the air, by M. J. Peyron.—Note on the floral polymorphism of aquatic ranunculi, by M. Louis Crié.—A study of the Quaternary deposits in the district of Perreux, east of Paris, by M. Emile Rivière.—Note on an experiment undertaken to determine the direction of the Atlantic currents, by the Prince of Monaco.—Observation of the crepuscular lights on November 2 and 16, in Paris, by M. A. Boillot.

BERLIN

Physical Society, October 23.—Prof. Neesen reported on the experiments he had made on sounding air columns, with the object of determining the relation of Kundt's dust-figures to the tone-pitch. By means of an electric tuning-fork, whose tone-pitch, through the imposition of weights, might be variously modified, the air was maintained in permanent vibration in a glass tube closed at the bottom by a membrane, and the intervals of the sand-ribs from each other measured. To further extend the scale of tone-pitches, rubbed pieces of wood were utilised as sources of sound. The very numerous measurements taken led to a negative result, no relation of the intervals of the ribs from each other to the tone-pitch could be established. On the other hand, however, the speaker succeeded in making some interesting observations of a different kind and prosecuting them to an important stage. He first established that the long-known wandering of the ribs in a permanently sounding tube stood in no demonstrable relation to the vibrations of the air, and in one and the same tube was found at one place directed one way, and at another place another way. Herr Dworzak's presentation of the matter, that this wandering of the ribs was induced by air-currents setting in at the wall of the tube in one direction, and at the middle in another, the speaker was unable to confirm. The cause of the wandering of the ribs could not be ascertained. On the subject of the origin of the ribs several observations had been made, at spots in the tube, namely, where the wanderings of the ribs issued in contrary directions, and where, accordingly, comparative rest obtained. Here, first, a cork sand granule was seen executing movements hither and thither, in which, shortly, ever more and more granules, and at last a whole series, took part. This layer of granules next began to roll up towards the sides, growing ever thicker in the process, and ending in the formation of a rib. The ribs further showed elevations of a character like to that of waterspouts, the branches of which, falling downwards, assumed the shape of whirls, and returned to the rib. On viewing them with intermittent light, these formations appeared at rest, when the number of light intermissions corresponded with the number of vibrations of the exciting sound. A very interesting phenomenon was observed on taking the measurements of pressure in the sounding-tube. A narrow glass tube, open on both sides, with an oil index, the movements of which were observed, served as manometer. No displacement of the index was ever noticed, but out of the interior end of the manometrical tube there appeared to issue a current of air impelling the cork sand a long way. This current of air was stronger when the mouth of the narrow tube was conical than when it was cylindrical. The current of air was present both when the upper end of the tube was open and when it was closed, as also when the lower end turned towards the source of sound was diverted from it, in consequence of an incurvation. The current of air was finally identified at all points of the sounding-air column, but the intensity of the apparent air-current varied according as the lower end was in the belly or in the node of the tube, and according to its length. The maxima of the current were more pronounced than the minima. If the upper end were likewise in the sounding-tube, then was there a current from the manometrical tube forthcoming. The index in the manometer, however, remained persistently unmoved, a demonstration that in point of fact there was no actual current in the narrow tube. The strength of the apparent air-current might be measured by little mills, and when small radiometers with paper wings were introduced into the sounding-tube, they fell into very lively rotation. If instead of full paper wings the radiometers had small conical paper tubes, directed all alike, they rotated just as fast, and in just the same manner as did the other radiometers. When, however, one approached the node of the sounding-tube, the rotation became slower, ceased, assumed the contrary direction, in order, after further progress, to pause again, and next pass into the former lively rotation. The fast rotation of the sound radiometers Prof. Neesen explained as anemometrical movements which, as was known, were independent of the direction of the wind. The contrary movement of the tube radiometers in the node were explained as determined by the currents of air in the little tubes which had been observed in the manometers as stated above; they entered into the phenomena in which the vibratory movements were less. The attractions and repulsions produced by the sound appear to be based on similar processes.

Meteorological Society, November 3.—With reference to a recent publication of Dr. Lender, Prof. Spörer made some observations regarding the line of demarcation which must be drawn between meteorology and hygiene, and by way of illustration related a number of personal experiences gathered in the course of his stay in the tropics, pointing out how the explanation of them did not properly belong to the office of meteorology.—A paper on the brown ring and the solar eclipses, by Dr. Zenker, who was unable to be present, was read. The abnormal sunset glows which had appeared in the skies since the autumn of 1883 and the brown-red ring round the sun were still visible, though in reduced intensity. The fact that these phenomena were not earlier observed showed that they owed their existence to something novel which had been introduced into the atmosphere, and were not at all due to the presence of ice-crystals or globules of fog in the higher strata of the air. The fine particles giving rise to the reflex-phenomena in question might be of terrestrial or of cosmic origin. The first of these two assumptions had to contend with the facts that the dust concerned with the phenomena kept so long afloat that the constituent dust-particles were of a very different character from that of the Krakatão ashes, and that it was at very great altitudes that they appeared to be suspended. Against the second of these assumptions—that, namely, of their cosmic origin—there was the fact of the absence of metallic particles from the dust and also the fact that the dust was found occurring likewise in lower strata. No decision had yet been arrived at in the matter, and it was therefore of great importance to determine precisely the altitude of the dust-cloud floating above the earth. The measurements hitherto taken had yielded very different results. In this respect it was a most striking fact that on one and the same day in Steglitz, near Berlin, the height of the reflecting dust was calculated from the glowing phenomena at from 2 to 17 kilometres, while in Dresden the glow was observed the whole night; and that for the end of the astronomical twilight about midnight, on taking a single reflection, the height of the reflecting surface gave itself as equal to 900 kilometres, and, on taking a double reflection, showed a height of from 200 to 300 kilometres. Dr. Zenker suggested that on the occurrence of the next solar eclipses observations of the brown ring be made. For the zone of totality he calculated the formulæ for the exact determination of the height of the dust-cloud. These formulæ were not communicated, because the paper itself would shortly appear in the *Meteorologische Zeitschrift*. It was only briefly mentioned that if during the totality the whole of the brown-red ring were seen, a height of $6r$ would be the result, r being the diameter of the cone of shadow. An exact representation of the total solar eclipse in the year 1886, visible in America, and that of 1887, visible in Europe and Asia, was appended to the paper.—In the discussion which followed the reading of this paper Prof. von Bezold referred to the fact that the brown ring was very difficult of perception in the plain, being not at all visible in Berlin, for example; while even at a slight elevation it could be very beautifully observed. He further advised caution against the assumption that the brilliant sunset phenomena were something entirely new. He himself occasionally observed such phenomena as far back as 1863, though it was formerly not possible to awaken general interest in the spectacle as can now be done. Regarding the brown ring, too, he conjectured that it had been formerly seen, though attention had not been paid to it.

THURSDAY, DECEMBER 3, 1885

THE ETIOLOGY OF CHOLERA

THE announcement by Dr. Koch, as chief of the German Cholera Commission, that he had discovered a micro-organism which was not only peculiar to cholera, but which had a causal relation to that disease, was all along felt by many to have been made on insufficient evidence, and in consequence the India Office in 1884 appointed Drs. Klein and Heneage Gibbes to visit Bombay, Calcutta, and other Indian cities, with a view of studying the disease from the micro-pathological point of view. Their report was received early this year, and whilst it supported Koch's statements to the effect that choleraic dejections were generally characterised by the presence of the comma-shaped bacilli which had been described, it distinctly denied many of the assertions which had been made by that observer, and it altogether set aside the notion that the comma-bacillus bore any causative relation to the disease. The point at issue was felt to be of such importance that the India Office somewhat recently appointed a Committee of physicians to consider the report made by Klein and Gibbes, and to advise them on the matter.

The Committee in question do not profess to have done more than to study the subject as it has been dealt with in the several reports issued by Koch, Klein, and Gibbes, and to communicate their views of the merits of the several reports to the India Office. They deal with the contentions of Koch under several headings. Thus, in the first place, they refer to his assertion that the number of comma-shaped organisms in the intestinal tissues and contents is in proportion to the acuteness of the attack, and that these organisms generate within the body a ferment by which the system is poisoned.

As to this, it is admitted by Klein and Gibbes that if all that Koch asserts on this point were correct there would be strong grounds for believing that the comma-bacilli must in some way or other be related to the cholera processes; but their observations are in direct opposition to the assertion made. As regards the intestinal tissues, and notably the mucous membrane, it was found that, in some most acute cases in which the post-mortem examination was conducted as soon as possible—at times in a quarter of an hour—after death, the comma-bacilli were only conspicuous by their absence; and that these organisms were only present in dead tissues, including the mucus flakes. Indeed, it is contended that the comma-bacilli are only putrefactive organisms; and the Committee, having these facts before them, express the opinion that no direct relation exists between the number of comma-shaped organisms and the gravity of the attack.

Another of Koch's contentions is to the effect that the comma-bacilli are not found except in connection with cholera. Now Klein and Gibbes maintain that these bacilli, or some that in morphological respects appear like them, are found in diarrhœa stools, that they have been met with in cases of dysentery and enteric catarrh, and that in other cases they have been found, together with certain putrefactive organisms, in as large numbers as in many cholera stools. And further, Klein has, since the issue of his report, found that by ligaturing a portion of the bowel of a monkey, large numbers of comma-bacilli were produced, and that these have been found, after cultivation, to present the same character as the so-called cholera bacilli. Besides which, Klein has found comma-bacilli, similar in appearance to those found in cholera, to be ordinarily present in various parts of the alimentary tract in health, and as regards some taken from the mouth, he has succeeded in cultivating them, and in demonstrating that their action on the media in which they grow is identical with that of the bacilli found in cases of cholera. And the Committee, whilst not convinced that the absolute identity of the two sets of bacilli has been proved, are inclined to agree with Klein's contention.

The third point examined is Koch's statement that the presence of comma-bacilli in a tank which supplied certain cholera-affected villages in Calcutta with water was, practically, a proof of the causal connection between the organisms and the disease. As to this, Klein and Gibbes report that they, too, examined the water from this tank, and that it revealed undoubted comma-bacilli in every respect identical with those found in choleraic dejecta; they further added that the water had been contaminated with choleraic evacuations, and that, notwithstanding these two conditions, its extensive use by many human beings had not been followed by a single case of cholera. The reporters hence submit that the water did not contain the cholera virus, and that this latter has nothing to do with the comma-bacilli. Similar evidence as to other tanks is also adduced, and it is added that these tank-commas, having been cultivated, are found to be identical with Koch's comma-bacilli. The question as to the existence of any causal connection between comma-bacilli and disease in animals as the result of inoculations is also discussed, and it is regarded as demonstrated that neither the alvine dejections of cholera nor cultivations of isolated comma-bacilli obtained from such dejecta are capable of producing cholera, nor indeed any disease resembling it.

The Committee, therefore, have concluded that, though comma-shaped organisms are ordinarily present in the dejections of cholera patients, they are not found in the blood or in any of the tissues, even when these are examined in a recent condition; that comma-shaped organisms of closely allied morphological appearance are ordinarily present in different parts of the alimentary canal in health, and can be developed there to an unusual extent in diseases characterised by hyper-secretion of the intestine; and that there is no evidence to show that the comma-shaped bacilli found in cholera induce that disease in lower animals or in man.

According to the Committee, we are now much in the same position as we were before Koch's experiments were instituted, in so far as the prevention of cholera is concerned; and Dr. Timothy Lewis, the Secretary to the Committee, and who has had a wide Indian experience in connection with the micro-pathological study of the disease, further points out that there is nothing new in Koch's observations except in so far as an ingenious and beautiful process facilitating the investigation of micro-fungi is concerned. Dr. Lewis asserts, indeed, that he had made hundreds of cultivations of the bacilli in question, and that he had long since arrived at the conclusion that they were identical with some of the minute vibrios which ha[s] so frequently been referred to by former writers as being present in cholera dejecta: the comma being, in short, nothing more than a segment of one of these vibrios which had become detached during the process used by Koch. It is true that Koch's friends deny that any comma found elsewhere than in the cholera intestine grows under cultivation, in the same way as the one he has described, but so far, this is a mere assertion, not a proved fact; and it is evident that we are but at the commencement of any proper apprehension as to the significance of these vibrios. This is pointed out in an appendix to the Committee's report, and the lines of future investigation into the subject are laid down. But for the present the prevention of cholera can only be found in the prosecution of well-advised sanitary measures, and whilst it is of the utmost importance that labours such as Koch and former investigators have carried out should be continued and put to the most rigid test, yet micro-pathology cannot, at present, be regarded as having made more than a small advance towards the solution of the question under discussion.

A MANUAL OF TELEGRAPHY

A Manual of Telegraphy. By W. Williams, Superintendent of Indian Government Telegraphs, &c. (London: Longmans, 1885.)

A MANUAL compiled to order for the use of the *employés* of the Department—very well written, very well printed, very useful to the Department, and very interesting to the technical reader. It embraces a general description of the apparatus used in India, the faults they experience, and the remedies they apply; a full account of the elaborate system of testing reared under the care of the late Louis Schwendler, the able electrician of the Department; and a clear account of the electrical phenomena which interfere with telegraph working and require watching and removal.

It is supplemented by an excellent *résumé* of the laws which determine the strength of electric currents under various circumstances, and a series of formulæ and mathematical solutions of various problems that occur in practice. It is in reality a primer to an admirable work on "Testing," written by Schwendler and edited by another very able electrician who died in India—R. S. Brough.

It is remarkable how India, practically isolated telegraphically from the rest of the world, originated and maintains a system *sui generis*. It was sown by O'Shaughnessy, it was nursed by Robinson, it is maintained by Cappel. It has had engrafted upon it much of the German element, due to the education of Schwendler in the great house of Siemens; but it remains quite distinct from the rapid system in use in England, and also from that in America—more Continental than English, and American only in its long circuits and sound reading. It has been singularly fortunate in the able officers that have served it, most of whom are highly educated gentlemen selected by competitive examination, and well trained in technical matters before assuming office. The proceedings of our societies, especially those of the Telegraph Engineers, contain frequent valuable communications from India, and this last volume fully maintains the reputation of the Department.

There are some curious errors, particularly among those rocks upon which so many young writers are wrecked, viz. *definitions*.

There is a strange, but excusable, confusion between *electrification* and *potential*, while there is an inexcusable confusion between *current* and *quantity*. Definition 1 says "*electric quantity* is the amount of electricity present in an electrified body," and definition 2 says "the unit of quantity or current is called an "Ampère, Weber, or Oerstedt." Now the unit of quantity is called a *coulomb*, and current is not quantity, but quantity per second, a very different thing, and is called an *ampere* only. It was called a weber, but this term has quite died out since the Paris Congress of 1881, and no one ever called it an oerstedt out of India. The relation between quantity and current is shown by Faraday's great law:—

$$Q = Ct$$

It is a pity that p. 5 cannot be reprinted. Definition 16 is curiously worded: "The unit by which capacity is measured is called a *farad*, or more generally for convenience a *microfarad*." A casual reader would think that the same unit is indifferently called a farad or a microfarad, whereas we learn later on that the one is one-millionth of the other.

At p. 57 we read of a very strange practice. The only cause of errors in the signalling of figures (on which, it must be remembered, the most important issues may depend) is due to a practice, unfortunately too common, known as "exaggerating signals," by which a letter is given more characters than it really possesses: for example, the letter *h*, a most common victim of this ill-treatment, is, by the addition of an extra dot, mutilated into the figure 5. We trust this strange practice is confined to India; we have never heard of it anywhere else.

The *résumé* of laws at p. 241 is very good indeed; but why denominate Ohm's and Kirchoff's laws, and not those of Ampère and Faraday?

The novel practice, in technical books, of printing notes as well as references on the margin instead of at the bottom of the page, has been adopted, and the convenience is certainly very considerable. The printing and get-up of the book are admirable. It should be added to every telegraph engineer's library.

OUR BOOK SHELF

Elements of Inorganic Chemistry. By James H. Shepard, Ypsilanti High School. (Boston: D. C. Heath and Co., 1885.)

THIS little book is evidently intended as a sort of mutual companion of the teacher and student, and is for beginners only, as the author informs us. It is, however, a mixture of elementary and somewhat advanced information on the subject, and certainly would be somewhat difficult for a beginner to be left alone with. The book is well supplied with questions for the student to attempt, and also with suggestions to the teacher as to where questions may be with advantage put. Most of the substances known as elements are mentioned, and their properties to some extent described, even including the so-called rare metals. A chart of "The Natural Classification of the Elements," according to "Mendelejeff," and an appendix on reagents is also included.

Numerical Exercises in Chemistry. By T. Hands, M.A., F.R.A.S. (London: Sampson Low and Co., 1884.)

THIS is a neat little book of easy arithmetical exercises on chemical problems which are likely to crop up in the course of laboratory work. The examples, about 650 in number, are to some extent original and partly collected from examination papers. They extend over a good deal of the physical ground more intimately connected with chemistry, and appear to be generally of a useful character. There is no attempt at theoretical instruction beyond what is absolutely necessary for setting out a question. The first four pages are given to exercises on the metric system, after which thermometers, heat, chemical equations, &c., are dealt with. The book will be very useful for students who have got a little way into the subject, but still in the position of beginners.

An Introduction to the Differential and Integral Calculus, with Examples of Application to Mechanical Problems. By W. J. Millar, C.E. (London: Blackie and Son, 1885.)

THIS is the second attempt within a very short time to give an elementary and, as far as possible, interesting exposition of the principles of the Differential and Integral Calculus. One cannot but feel sympathy with the authors of such attempts, for, sooth to say, we often find writers on the less elementary branches of mathematics anything but good teachers or editors of students' text-books.

The present little work has the peculiarity that, being written for engineering students, its illustrations are mainly such as can best be appreciated by those who have an acquaintance with applied dynamics. It is clearly written, the examples are well chosen, and it is on the whole wonderfully accurate, considering the appearance usually made by practical men when dealing with pure mathematics. On page 7 no distinction is made between the increment of x and the square of the increment of x; on page 12 there is a faulty investigation of the rule for the differentiation of a quotient; and one or two others might be specified. These do not detract much, however, from the value of the exposition as a whole, and we cordially hope that the little book may attain its object of smoothing and rendering attractive to practical engineers the rather forbidding pathway leading to the higher mathematics.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Whole Duty of a Chemist

I CANNOT complain if the address which I delivered a few weeks ago to the Institute of Chemistry, although it received an extent of encomium for which I was quite unprepared, should meet here and there with adverse, not to say unfriendly, criticism. Naturally enough, the inculcation of sturdy self reliance is displeasing to the new apostolate of sponging upon others, though it scarcely, I think, justifies a resort to the dialectic juggle of representing the defence of one side of a chemist's duty as meant to be a deliberate expression of "the whole duty of a chemist." The Chemical Society takes cognisance of chemists in one aspect of their work, the Institute of Chemistry takes cognisance of the same individuals in another aspect; and one really need not be a conjuror, though it may put some strain on the fair-mindedness of an editor, to perceive that an address intended for the one organisation would be unsuitable for the other. That distinguished man, the late Dr. James Young, F.R.S., whom you so complacently sneer at, was not a professional chemist at all, but a manufacturing chemist. He was a first-rate manufacturer, whereas Reichenbach was but a third-rate or fourth-rate investigator, if so much; and, your opinion notwithstanding, it is commonly held that the first-rateness of the one man in his own walk more than counterbalanced whatever weight attached to the higher walk of the other. I may cite for your information Sir Frederick Abel, Dr. Frankland, Prof. Dewar, and the late Dr. Stenhouse, as being eminent professional chemists. Though of high repute in forensic circles, I am not aware of their being never heard of at the learned Societies; but I am aware that, in common with other leading chemists of the country, they have had the bad taste to be contemptuous of your own contributions to chemical science. Can it really be that this circumstance has affected unconsciously the spirit of your leading article? I would suggest, moreover, for your editorial consideration, that to supplement criticism of an author's performance with flippant insinuations as to his personal conduct and career, is hardly in accordance with the best traditions of scientific journalism; while it constitutes undeniably bad art, as implying that the production criticised did not of itself afford adequate opportunity for attack, even, of course, with an editor's happy privilege of misrepresentation. As regards the reflections so unmistakably made on myself personally, I have little fear that the irreproachable tone of your remarks will serve to suggest the measure of their trustworthiness; and will only observe "happy are they that hear their detractions, and can put them to mending." As regards, however, your disparagement of the chemical profession at large, from which, I trust, it may not suffer beyond hope of recovery, I would venture to remind you that even that other profession, of which you are so magnanimous a member, has had its calumniators; and the words of a well-known satirist of the last century are considered by some to be as applicable now as ever, that "Of all the cants which are canted in this canting world, the cant of criticism is the most tormenting." Sterne was, happily, unacquainted with the cant of scientific mendicancy, or he might have added that that also was a very fine cant in its way.

WILLIAM ODLING

Oxford, December 1.

[We print the above without comment except on the two following points. Dr. Odling has entirely misunderstood the allusion to the late Dr. Young: no sneer was intended, as will be obvious on a perusal of the whole paragraph. He has also taken as personal to himself remarks made on types not individuals.—ED.]

A Stray Balloon

THE *Times* published on September 29 a short extract from the *Bermuda Royal Gazette*, communicated by me, describing the appearance of a balloon, passing over Bermuda on August 27, and which I suggested might be one of those which ascended this year in England or France, and had not been subsequently heard of. This was followed by a letter from Mr. Charles Harding, F.R.Met.Soc., commenting on the "extreme improbability" of a balloon crossing the Atlantic, and even adding that "a little practical experience in ballooning suggests it to be thoroughly impossible."

As the columns of the *Times* are hardly suitable for the discussion, may I ask that you will allow me to make public through NATURE the further information I have received on the subject.

First, the *impossibility* is, I think, disposed of by the fact that one of the balloons sent up from Paris during the siege did actually travel rather more than half the distance, having descended in Iceland, where it was found long after. We know not how long either balloon was on its course, but it would be bold to assert that if one balloon can float four or five days another cannot float ten days. We know nothing of the exceptional conditions which prolonged the buoyancy: an unusually good varnish, peculiar folding of the silk in its collapse, a film of ice, may all be supposed capable of checking the escape of the gas. However, we have first to verify the fact. On the appearance of Mr. Harding's letter, I wrote to the Hon. W. H. Gosling, of Bermuda, a gentleman well known for his interest in matters of scientific inquiry, and begged him to investigate the story. His reply is before me, dated November 4:—

"On Saturday, October 31, I visited the spot where the balloon was alleged to have been seen. I am convinced of the fact. The place is a high hill east of the lighthouse. The two women were accidentally out in a field near where they live. Mrs. Bassett saw the object in the sky, high up, many times higher than the light. It seemed to her under the clouds. She knew nothing of balloons, and thought a whirlwind had raised some nets from the sea, as it appeared to her an object from which nets were suspended. She fancied she saw the corks of the net hanging at the bottom." (Mr. Gosling here remarks, "No doubt the basket, or the remains of it, of the former account, with chains, were the suggestion of her husband, who did not see it.") "She called her neighbour, and they both watched its course out over the sea, south, until it disappeared from view, which would not take long, as a brisk north wind was blowing. No one else seems to have seen it, nor would these, had not one of them accidentally looked up.

"I cannot hear of any balloon having been sent up in America, but on September 17, three weeks later, a balloon impaled itself on a church steeple in Chicago, U.S. The basket contained some torn clothing, and a branch of oak, as if it had come in contact with trees. The wind here on the three succeeding days was east, south-east, south. I suppose you know of the report of the missing balloon from Paris, in July, seen afterwards in the Bay of Biscay, going west."

So far Mr. Gosling, who incloses an intelligent letter from Mr. Robert T. Bassett, husband of the first witness, giving some compass bearings.

The *Monthly Weather Review* of the United States for September, which has not yet reached England, may perhaps throw light on the probability of an object seen floating in the air over Bermuda on August 27, whether arrived from Europe or not, being transported to Chicago by September 17. The coincidence is remarkable, but I know nothing of this incident beyond Mr. Gosling's mention of it. High winds with heavy rains prevailed in the South Atlantic and East Gulf States of the American Union on August 31, and the centre of a cyclone travelling in a north-easterly direction was then off the coast of South Carolina. A balloon drifting south from Bermuda on August 27 would be caught in the south-east quadrant of such a cyclone; and if it kept afloat long enough would, in a few days, be landed in a north-westerly and then in a northerly direction. The conditions of the question oblige me to assume that it is not a physical impossibility for a balloon, with very little weight attached, to drift about for weeks; but the singularity of the occurrence calls for every investigation, and should you admit this long communication, I hope that further evidence may be procurable from Chicago. J. H. LEFROY

Par Station, Cornwall, November 23

"Evolution without Natural Selection"

BELIEVING as I do that the words of a reviewer should be final, it is with no small amount of hesitation that I pen the following few remarks on the review of my little work entitled "Evolution without Natural Selection," which appeared in NATURE of November 12 (p. 26). The curious way in which my book has been misunderstood, and my consequent endeavour to put matters in a clear and impartial light, must be my apology for taking up your valuable space. In the first place, Mr. Romanes finds fault with the title of my book; but why, it is hard to conjecture. I venture to assert that nine-tenths of the matter it contains attempt to illustrate the operation of evolution without any natural selective process, as any impartial reader must admit; consequently, I absolutely deny that I only reserved a few odds and ends of small detail which I ascribed to other agencies. I might also state that I had a reason, and I think a very good one, in confining my remarks exclusively to birds. Had I elected to cover a wider area, I could have shown that these "odds and ends," as Mr. Romanes somewhat contemptuously calls them, do not by any means exclusively apply to birds, but to species in every other department of natural history. Mr. Romanes goes on to say that "It is the very essence of the Darwinian hypothesis that it only seeks to explain the apparently purposive variations, or variations of an adaptive kind; and, therefore, if any variations are taken to be non-adaptive, *ex hypothesi* they cannot have been due to natural selection." Precisely. And it was the immense amount of what I may call non-purposive variation which forms the line of demarcation between such vast numbers of species that I have attempted to explain by other agencies when natural selection utterly fails to do so. I most emphatically deny that I ever said, or even inferred, that these variations are "for the most part rare," as Mr. Romanes leads the reader of his review to suppose. All naturalists who are in the habit of working through large series of specimens are well aware of the immense number of species whose claim to rank as such is based upon their slight variation from a dominant type. It took me five years' hard work amongst tens of thousands of specimens to arrive at the conclusions expressed in my little book; and, in my opinion, no naturalist is qualified to write on these subjects without serving such an apprenticeship. That is why, as a specialist, I confined myself to birds alone for my examples. In the face of the array of important facts which I endeavoured to chronicle, it seems strange for a naturalist of such standing as Mr. Romanes to state that these facts "may be freely presented to the anti-Darwinians." Why "anti-Darwinians," Mr. Romanes? No one but an evolutionist (and most evolutionists are surely Darwinians) would attach any importance to these "trivial variations," and consequent intergradation of specific forms. Mr. Romanes is careful to point out how Darwin himself admits that if these trivial specific characters are "really of no considerable importance in the struggle for life, they could not be modified or formed through natural selection." Now probably it is no exaggeration to say that at least one-third of the known recognised species absolutely rest on these "trivial specific characters." If they have not been evolved by natural selection, I maintain that other and as equally potent agents as natural selection have been at work. The object of my little book was to try and explain them.

A word as to the *cause* of variation. No one who understands anything at all about the theory of natural selection ever supposes that it is an original cause of variation. Mr. Romanes cannot have read my essay very closely, for had he done so he would have seen that I drew the reader's attention to this fact (*conf.* p. 49). The *cause* of variation is quite another question, and one which after all did not materially concern my treatment of the subject. Nevertheless, I alluded to the use and disuse of organs as a direct cause of variation. I would also wish to point out that Mr. Romanes is entirely in error in saying that I "everywhere speak of isolation as the *cause* of minute specific characters." All I endeavoured to show was that isolation can preserve a non-beneficial variation when it has arisen, just as much and effectually as natural selection can preserve a beneficial variation.

Did space permit, I would like to say a few words on climatic variation, and the probable times at which natural selection is most active in the evolution of species; on both which subjects Mr. Romanes unconsciously misrepresents me. My reviewer has nothing whatever to say on my treatment of sexual selection; the use and disuse of organs, inter-crossing, the local distribution of specialised forms, polar centres as points of dispersal, &c.

Mr. Romanes seems to think that my little book was written in an anti-Darwinian spirit. Nothing of the sort. On my last page but one I said, "Let it be clearly understood that not one single syllable in the foregoing pages has been written antagonistic to Darwin's theory of Natural Selection. All I have done has been to attempt to explain certain phenomena which the Darwinian hypothesis can never do, and which its supporters ought never to have attempted to make it explain." If I have not made my meaning plain, and thus left myself open to misunderstanding, it will be a source of great regret. Science and simplicity should be synonymous. In the French edition, shortly to be published, which is now being translated by Dr. Varigny, of Paris, I hope to make a few corrections and additions, which I trust may possibly render me less liable to be misrepresented in future. CHARLES DIXON

London, November 21

I FREELY admit that the impression left upon my mind after reading Mr. Dixon's essay was the same as that which was first conveyed by its title—viz. that the author supposed his work to be, if not "antagonistic to Darwin's theory of Natural Selection," at all events, as I expressed it, "an important emendation of Darwinism." My object, therefore, while reviewing the essay was to show that this is a character which does not belong to it. If I have misunderstood the meaning of its author on this fundamental point, I should have been glad to have received a more express statement of the fact than appears in the above letter; for I might then have felt that Mr. Dixon's views with reference to the value of his work are in full accordance with my own. As stated in the review, I consider his facts most interesting as examples of trivial specific characters—or slight variations of a fixed kind—due to variation presumably unaided by selection; and when I said that such facts "may be freely presented to the anti-Darwinians," I meant that they might be so presented to any one who supposed them anti-Darwinian. It appeared to me that Mr. Dixon himself regarded them in this light (though not as anti-evolutionary), at all events to the extent of imagining that they had not been sufficiently recognised by Darwinians. But, as I have said, if such is not his meaning, I am very glad to find myself in agreement with him upon this point.

I spoke of these trivial specific characters as "odds and ends," and as of "comparatively rare occurrence," because, although both numerous in themselves and of importance for the purposes of detailed classification, they are insignificant when compared with the whole organising work of natural selection. And if, as Mr. Dixon now repeats, it was the object of his little book "to try and explain the agents" (*i.e.* the *causes*) producing these non-purposive specific characters, I can only repeat that in this respect his book has failed in its object. Lastly, my only reason for not mentioning Mr. Dixon's views on natural selection, &c., was that I found nothing in these views particularly deserving of mention. GEORGE J. ROMANES

On Radiation of Heat from the Same Surface at Different Temperatures

WITH respect to my recent communication to you on the subject of radiation of heat at different temperatures (p. 85), I wish to remark that the temperature given as the temperature of the surroundings must be taken as only approximate. A remark to this effect was in fact included in the first draft of my note to you, and was inadvertently omitted in the final copy.

If the glass envelope surrounding the wire were perfectly diathermanous, and likewise the intervening air, then the temperature of the surroundings would be simply that of the walls of the room. As it was there is a great difficulty in saying precisely what is to be taken as the temperature of the surroundings. The glass envelope becomes heated to some extent, and will return a certain amount of radiation to the wire. When the vacuum is nearly complete, however, the heating of the glass is slight, and is very small in comparison with the heating when the vacuum is only partial.

The reason I have not used a metallic envelope blackened inside and cooled outside, is that it is very difficult to attach such an envelope in a satisfactory way to the Sprengel pump. I am, however, hopeful of being able to overcome this difficulty.

November 28 J. T. BOTTOMLEY

THE NOVEMBER METEORS

THE watch which was kept on November 27 in the hopes of seeing a shower of meteors from the stream connected with Biela's comet was very amply rewarded. At the Royal Observatory, Greenwich, the weather was somewhat unfavourable, the sky being partly clear only at intervals, yet, when the meteors were first seen, between 6h. and 7h. p.m., they were appearing at the rate of from 30 to 40 per minute. The average brilliancy of the meteors was remarkable. The radiant-point as determined at the Greenwich Observatory from a number of paths was estimated to be about R.A. 20°, Decl. 49° N.

We have received the following communications with reference to the meteor showers:—

THE great display of Andromedes, or meteors of Biela's comet, which occurred on the evening of November 27 last, and which fortunately has been widely observed, adds another corroborative link to the theory, already demonstrated by facts, connecting comets and meteors. Not only does this stream exhibit a perfect orbital resemblance to that of the comet with which it has been associated, but it recurs only at the special times when, according to computation, the comet is in the vicinity of that region of its orbit encountered by the earth on November 27.

Many meteors appeared on the evening of November 26 this year, the hourly rate, as estimated at Bristol, being considerably over 100, and they nearly all belonged to the shower from Biela's comet. But the display on that night was not of very exceptional richness, though it gave distinct intimation of what was to follow. The meteors of November 26 were simply the *avant couriers* of the advancing host, for, as soon as twilight deepened on the following evening, it was seen at once that the shower had greatly intensified. Meteors were falling so thickly as the night advanced that it became almost impossible to enumerate them. Frequently they came in simultaneous groups of five, seven, or ten, all radiating from the immediate region of the star γ Andromedæ, and appeared in every quarter of the firmament with that uniform slowness of movement which is a peculiar feature of the shower.

The prediction that such a display would occur has thus been completely verified, and the character of its leading features has been precisely conformable to anticipation. For not only has a meteor-shower occurred at the appointed time, but it has coincided in all its salient attributes with what has been expected. The radiant-point near γ Andromedæ has been accurately marked, as on November 27, 1872, and the meteors have presented the same visible traits of appearance.

As to the strength of the display, it has been variously described, but there can be no doubt, from the observations, that it will rank in importance with any similar phenomenon recorded in modern times. At stations where the clearness of the atmosphere permitted its full grandeur to be recognised, it would seem that about one meteor per second was counted, and this means a rate of 3600 per hour.

These facts warrant us in the assumption that the earth has recently encountered a very dense region of the meteor-stream. Notwithstanding that these meteors have to overtake the earth in her orbit, and that they therefore travel with the minimum velocity (about eleven miles per second) possible in the case of such bodies, they have returned in surprising abundance. A far more attenuated system, encountering the earth under similar conditions to the Leonids of November 13, which directly meet the earth in her path, must have originated a more numerous display, because a far greater range of such a stream would be traversed in the same interval. Here the velocities of the earth and meteors would be combined by the favourable circumstances of the *rencontre*, and the earth would really penetrate the stream at the rate of some forty-four miles per second. But in the instance of the meteors from Biela's comet, they are travelling in the same general direction as ourselves, and it is only their greater native velocities which enable them to catch up the earth, and become visible in the form under which we have just observed them.

When all the accounts of this remarkable display become available for reduction, it will be important to compare them with those of its predecessor in November, 1872. Though the present shower has been an obvious repetition of the one just referred to, it may exhibit some differences which it will be essential to investigate. In one respect certainly there would appear to be a want of accordance. We refer to the relative durations of the two displays. In 1872, on November 26 and 28, that is, on the nights preceding and following the great shower, very little sign of it appears to have been observed. It was immediately confined to the night of November 27. In NATURE, vol. vii. p. 104, Prof. Herschel writes:—

"On the evening of the 28th [November, 1872], Mr. Greg watched for shooting-stars, and for any remnants of the star-shower of the previous evening which might be visible, but although the sky was quite clear, he failed to see any meteors. A strict watch for outlying meteors of the shower was also kept by two observers at Hawkhurst, in Kent, on the evening of the 28th, where the sky was quite cloudless between 9h. and 11h. 15m. p.m., but without success, only four shooting-stars of ordinary character being visible."

Prof. Herschel also quotes some observations proving that on November 26 of that year, meteors were singularly rare, and justly concludes from this that the display was confined to an interval of forty-four hours. Now the recent phenomenon was already a conspicuous shower on the 26th, when it was observed at Bristol at about 8.30 p.m., and on the 28th, in a four-hours watch before 11.30, 55 Andromedes were counted in a cloudless sky. We here have a period of fifty-one hours for its observed duration, but there is not the slightest doubt from the activity it exhibited at the opening and termination of the observations this year, that the shower must have been probably visible both on November 24 and 25, and also on the 29th. At Bristol the sky was overcast on these dates, so that the progress of the display during its complete rise and decadence could not be observed. It is certain, however, that it extended over several nights, and that its increase was more gradual, as in the case of the August Perseids, than its decline.

The outlying members of the shower observed at Bristol in the very clear sky of November 28 this year were extremely faint, the majority being of the 5th and 6th magnitude. It is therefore suggested that on the environs of the denser part of the stream, the meteors are of very diminutive size, and this may possibly have enabled them to elude detection at places where the atmosphere was not very clear. W. F. DENNING

AN extraordinarily bright display of Cassiopeiad shooting-stars occurred this evening, commencing, I am told, as soon as darkness set in, at about five o'clock. The sky was then cloudless here, but owing to street-lights I missed observing them between five and seven, and until informed of their appearance a little after half-past seven o'clock. Reaching an open space, and looking up at Cassiopeia, just overhead, I then counted about twenty meteors, all with short courses near that constellation, in the four minutes onwards from 7.40. Such a thick haze overspread the sky except just round the zenith, that only the bright stars of Cassiopeia and two in the Square of Pegasus (β Pegasi and α Andromedæ) were visible there; but several first and second magnitude meteors of the display which proceeded at the same rate until 7.50, left streaks on their short courses visible for two or three seconds through the haze, and these being sometimes actually in sight in groups together, made the direction of radiation very easy to determine. The thickening haze, however, hid the stars so completely at the latter hour, and afterwards, that further observations of the shower for the night have proved fruitless.

To my surprise, this active meteor-shower was diverging, not from the usual Biela radiant-point near γ Andromedæ, but the short meteor-tracks all streamed away from Cassiopeia! This was conspicuous in the meteors near Cassiopeia which travelled thence, as most of those visible did, westwards and southwards towards the Square of Pegasus across Honores Frederici, and eastwards and northwards across Camelopardus and Custos Messium. Although no faint stars in sight allowed their courses there to be regularly mapped, yet, from such a short collection of very good accordances for fixing it very nearly, I would place the radiant-point (by rough eye-estimation only) very near α, or between ζ, η, and θ Cassiopeia, which is about 15° from the Biela radiant-point near τ Andromedæ.

In his "Periodische Sternschnuppen," published at Aix-la-Chapelle in 1849, Heis described a radiant-point of several meteors seen there by him on the nights of December 8 and 10, 1847, between γ and τ Andromedæ, as a prominent one on those nights; and on the evening of November 30, 1867, Zezioli, at Bergamo, mapped a number of meteor-tracks, from which Prof. Schiaparelli obtained a well-marked radiant-point position closely agreeing, like Heis's, with the subsequent exact determination of the place of the "Andromede" star-shower's radiant-point made by numerous observers of the shower's great return on November 27, 1872.

Besides the radiant "A" in Andromeda, seen on the nights of December 8 and 10, 1847, Heis also described, in the same work, another, "C," close to α Cassiopeiæ, as conspicuous on the nights of November 12 and 13, in the years from 1839 to 1847; and he notices that Danse (*Comptes rendus*, vol. v. p. 759), on November 15, 1837, observed a shower of seventeen shooting-stars in a minute and a half diverging from the constellation Cassiopeia. In connection with the December epoch it is also noted that of a large number of meteor-tracks observed by Herrick at Newhaven, U.S., on December 7 and 8, 1838, about three-quarters diverged from the principal stars of Cassiopeia, and that Flaugergues, at Toulon, in France, made a similar observation on December 6 of the same year, 42 meteors, about 9 o'clock, falling vertically from the zenith, and 31 of them on nearly parallel courses from about Cassiopeia's place in it (as the account implies) between the Milky Way and the Square of Pegasus.

Although the connection of this "Cassiopeiad" stream with Biela's comet would seem, from the position of its radiant-point, to be somewhat doubtful, yet the occurrence now, as it appears, of a shower with nearly the same radiant point on the night of the famous Biela star-shower's date in 1872, makes the probability much greater than before that the "Cassiopeiads" of December 6 to 10 and the "Andromedes" of Heis, belonging to the same date and to November 27 to 30, may not be unassociated star-showers, but that both may possibly have had their origin in some bygone disruptions of Biela's comet! The position of this star-shower's radiant-point will, it is to be hoped, have been determined accurately by more fortunate observers than myself of its very striking apparition, so as, if it befits them, to corroborate these slight observations generally, and to fix the shower's centre of divergence with the astronomical position which is most desirable from these suggestive indications.

Four Leonids, varying from first to third magnitude stars in brightness, and leaving no streaks, were seen here between 2.10 and 2.50 a.m. on the 15th inst., together with two small sporadic meteors, in a clear moonless sky. They indicated plainly, by the accordant radiation outwards on a map of their long swift courses, from a moderately wide area in Leo's Sickle, a slender recurrence of that great star-shower this year. Its maximum now appears to present itself at least as distinctly on the morning of the 15th, as on that of the 14th of November, as the nodal line of the meteor-stream advances. Its short-lived displays, it may be gathered from this regular progression, need scarcely now be looked for any longer, on that account, on either of the historically famous dates of the 12th and 13th of November, of its once pre-eminently grand and imposing exhibitions, while a centenary view of one of those is not actually now a very distant event to look forward to on a coming 15th of November morning in the year 1899.

A. S. HERSCHEL

Newcastle-on-Tyne, November 27

P.S.—*November* 28.—On looking at the stars in a clear sky to-night, I find that those described above as having been just visible near Cassiopeia were not chief stars of the Square of Pegasus, as supposed, but bright stars in Cygnus and Cepheus! Instead of crossing Honores, therefore, the chief meteor-flights of the stream observed were shooting from the true Biela radiant-point near τ Andromedæ, past Cassiopeia into Cepheus. Other stragglers there certainly were, whose general radiation from Cassiopeia could not be thus accounted for. Just similar variations of direction, however, were common among a rather large proportion of the "Andromedes" in the great shower of November 27, 1872, which had rather an average than a very sharply marked radiant-point in Andromeda. There appears no reason to doubt, therefore, that on this occasion also the shower proceeded from the same prevailing centre of divergence.

From many observers' descriptions of it here, the present shower would seem to have been hardly, if at all, inferior in any respect—of duration, of brightness and multitude of its meteors, or of persistency in the light-streaks left upon their tracks—to the great and well-remembered display of the Biela's comet meteor-shower in November, 1872.

AS you may be desirous to make known any observations respecting the meteor-shower of the 27th inst., I beg to furnish you with those noticed by myself.

At sunset the sky was overcast, but happily at 6.30 p.m. the clouds dispersed, when the phenomenon was seen here in full splendour; the heavens were alive with the meteors making their rapid appearance and extinction.

My attention was attracted chiefly to the constellations of Cassiopeia, Andromeda, and towards Perseus, from whence the most brilliant portion of the shower was in operation, and from that locality the most conspicuous meteors shot forth. Selecting the most remarkable out of the numerous luminous trains for their length of traverse, and conceiving the line of direction to be thrown backwards, the convergence of these trains concentrated towards a point in Andromeda, in accordance with the position of the radiant-point as predicted in the Dun Echt Observatory Circular.

The paths taken by the above meteors were, in many cases, directed towards the southern horizon, and several towards the Pleiades in the east, from the radiant-point; others flitted away to every point of the compass, exhibiting longer or shorter trains during their ephemeral existence.

The general illuminating effect produced by the shower was appreciable, but it was not very powerful; and with regard to the colours which were exhibited in the luminous trains, my views combined with the opinions derived from other observers coincide—that the colour aspect of these transient illuminants varied apparently between golden and very pale-green tints.

But with reference to the zenith and its surrounding region, it was noticeable there that the conditions of the meteors had other characteristics, inasmuch as they were almost devoid of path or connection with any radiant-point, they were remarkably numerous, a great proportion of them exhibited no more than feeble flashes or scintillations of white light, the display was maintained with great rapidity and continuously.

It was also noticed that an erratic meteor was seen occasionally taking an independent course of considerable length, about 45° of arc, sometimes at low elevation, making an acute angle with the horizon.

About 7.15 p.m. clouds obscured the sky for the night, so I did not see either the beginning or the termination of this interesting phenomenon.

Comparing the great display of meteors which I observed in November, 1866, it was in all respects more magnificent than this recent shower. I could not on this occasion define any head or nucleus to any of the luminous trains, but this feature was remarkable in the large meteors of 1866.

As a single observer, it was impracticable for me to attempt any enumeration of the enormous number of meteors, and to observe the prominent features of the phenomenon at the same time. At midnight it was blowing a strong gale from the south-west; thick weather, with a mild temperature of 53°.

ERASMUS OMMANNEY

Yarmouth, Isle of Wight, November 29

THINKING, from the character of the weather on the night of the 27th, that opportunities of seeing the late splendid display of meteors may have been extremely local, I have taken the liberty of forwarding my notes of them as I saw them here from between a little before 6 p.m. until 7.35 p.m. How long the shower had been going on before (attracted by the cries of some passing boys) I looked out, I cannot say, but just before six when I did so, the sky was covered in many places with a thin haze, through which the larger stars and planets were looking greasy, as sailors say, while in nearly every direction meteors were gliding and bursting from a point a little to the eastward of the zenith toward the horizon; the meteors varying in brightness from that of the planet Venus to the faintest streaks of light. The larger ones were very like pale inverted rockets, having trains of many degrees in length, and often prismatic in colour; that is, near the head the light of the train was bluish, blending from green to yellow, followed by rose or crimson sparks. In many cases this train was visible for quite thirty seconds after the star was burnt out, first as a bar of warmish dusky light, and often becoming curved, as though by wind, as it faded away.

The silence of the display was almost oppressive, as one expected each moment to hear the bang of fireworks. During most of the time masses of luminous-looking vapour floated slowly across the sky. Some of the meteors seemed to burst end on, right over head, and though, being foreshortened, these left no train, yet they were among the brightest. I noted a considerable variation in the speed of the meteors, and am inclined to think that those which appeared farthest off moved slowest. It was next to impossible to say in which direction the star rain was thickest, for just as one was trying to make up one's mind upon this point, a troop of stars from an unexpected part of the sky would appear. Other observers may be able to speak more positively than I can upon this subject; but my impression, as well as that of those who saw them with me, was that they streamed down in groups of two, three, and four toward almost every point of the compass. About 7.20 p.m. the number seemed to become rather less, and at 7.35 this was markedly the case, though they were quite frequent enough then to have attracted attention any other night. Shortly after 7.35 the sky here became overcast by a storm-cloud, and it has remained so ever since, blowing a hard gale at S.S.W.

ROBERT LESLIE

Moira Place, Southampton, November 28

A BRILLIANT display of the Andromedes was seen here on the night of November 27 from about 6 p.m. to 9 p.m., after which time the sky was clouded over. During a walk of ten minutes (from 6.20 to 6.30), facing the north-west, I counted 150 meteors within that half of the visible heavens; and as they appeared to be nearly if not quite as numerous in the other half their total number would not be less than 1500 per hour. The radiant point was almost directly overhead. The meteors varied greatly in size, many being very small and faint. The larger ones left bright trails of a white or bluish colour. I observed one only in an opposite direction, and none with curved or zigzag paths. The shower was less grand than that of the Leonids in 1866, in which there was a larger proportion of brilliant meteors, many of them coming in flights of three to six at once, all near together; but with that exception the display of the Andromedes this year was the finest piece of celestial pyrotechny I have ever had the good fortune to witness. We seemed to stand under an encircling canopy of dropping lights.

Birstal Hill, Leicester, Nov. 28 F. T. MOTT

AN extraordinary meteoric display was visible here last night. I first observed it at 6.40 p.m., and was watching it at intervals for more than an hour later, when the sky became overclouded. Altogether the number of shooting-stars was immense. Unlike the correspondent of the *Daily News*, who observed a similar phenomenon at Naples the same night, I was unable to count the number per minute. Appearing suddenly, and often many at a time, in all parts of the heavens, from the zenith to the horizon, they quickly disappeared from view, the distance travelled not being more than a few degrees in any case. Some were much more luminous than others, and all in their passage through the air were followed by the usual trail of light. E. F. BATES

Leicester, November 28

THOUGH densely cloudy during the afternoon of the 27th, the sky became clear here about 6.30 p.m., when great numbers of meteors were to be seen, falling at the rate of fully 60 per minute, many being of great brilliancy. During the evening their number gradually decreased, till towards 10 o'clock very few were visible. The sky then again became overcast. PERCY T. INGRAM

Belvoir Gardens, Grantham, November 29

THE star-shower predicted by several astronomers was well seen here on Friday evening last. When first observed, at 5.30, the rate of fall was 25 per minute; the numbers, however, increased rapidly during the next half-hour, till, at 6 o'clock, more than 100 meteors were counted in a minute.

At 6.20 a marked decrease in the intensity of the shower was noted; but at 6.38 the numbers once more increased, till a rate of 70 per minute was attained; after this, however, they gradually diminished as the hours went on. It is right to mention that the numbers given above are those of the meteors seen by an observer looking towards the east; they do not represent the total number that fell at these two periods.

The radiant-point, as indicated by the position of several meteors which suddenly flashed out without sensibly changing their position, was close to γ Andromeda, or, more exactly, R.A. 21°, N.P.D. 46°.

Most of the meteors were mere "shooting-stars"; a large number, however, had brilliant phosphorescent trains, which continued to glow for several seconds after the meteors themselves had vanished. Occasionally one of the trains would break up into fragments, and in one instance a curious spiral form was assumed.

A special feature of the shower was its varying intensity, and that more particularly between 6 and 7 o'clock.

JAMES SMIETON

Broughty Ferry, Dundee, November 30

OUR Paris Correspondent writes:—The shower of falling stars has been observed at a number of French stations—Toulouse, Central France, Tunis, and Algiers. The point of emanation was, in the case of some of them, between Andromeda and Cassiopeia. In Paris it was not observed, owing to the foggy state of the atmosphere, and no balloon observation having been tried.

The following letters on the meteors appeared in the *Times* of Saturday:—

Mr. T. G. Dyson, of 1, Rothesay Villas, Windsor, wrote on Friday night:—"I was fortunate in witnessing this evening from 6.15 to 6.40 a most magnificent shower of stars, which might be compared to a flight of swallows, with a lull of a few seconds between each flight. Although the sky was anything but clear—only stars of the larger magnitude being visible—the meteors were brilliant, and in many instances left a distinct trail behind them. The direction was principally from east to west, varying to north-west."

The Leicester Correspondent of the *Times* telegraphed last night:—"A remarkable display of meteors was witnessed in Leicestershire to-night from dusk until a late hour. The display was most brilliant towards the western horizon, the meteors falling in perpetual showers, with brilliant trails, like a very fine display of fireworks."

A Reuter telegram from Athens, dated November 27, says:—A brilliant shower of meteors was observed here to-night."

A Newcastle-on-Tyne correspondent telegraphs:—"There was a splendid meteoric display here. I saw about 500 an hour. Radiating point Cassiopeia."

Prof. Pritchard, of the University Observatory at Oxford, telegraphs that he counted 251 meteors between 6.34 and 6.39 p.m., and 305 between 7.14 and 7.19.

IN case no one else may have reported the complete fulfilment of the prediction suggested by Lord Crawford's Dun Echt Circular allow me a few lines to do so.

I did not begin to observe systematically until nearly 8 p.m. (7h. 58m.), when I found that, confining my attention to one-third of the sky (south-south-east to west-north-west), and computing therefrom, meteors were falling at the rate of 33 a minute. Shortly after this they became more numerous, and from 8h. 5m. to 8h. 10m. they were falling at the rate of 56 a minute (nearly one a second), or more than 3000 an hour. From 8h. 30m. to 9h. 30m. the view was much hindered by cloud, but it was evident that the number was decreasing. From 9h. 30m. to 10h. the average fell to about 12 a minute, or scarcely a fifth of what it was at 8h. 5m.; and shortly after 10 p.m. the sky became entirely overcast.

I well remember the glorious shower in 1866. On that occasion the meteors were both larger and more numerous than they have been this evening, but occasionally they were very frequent—for example, at 7h. 59m. five were visible in less than two seconds (the precise period was one second and six-tenths).

G. J. SYMONS

62, Camden Square, N.W., November 27

In Paris, according to the *Times* Correspondent, the sky was overclouded all Friday night, but the meteor-shower was seen to advantage in the South of France, in Belgium, Germany, Spain, and Italy, as also in Tunis, where the natives were much startled. At Châtelhérault the meteors were well seen. At Cologne, Dr. Klein counted 636 between 6 and 7 o'clock, though the sky was at times overclouded. Most of them moved very slowly and left a trail of light, which quickly disappeared. Four were large and brilliant enough to be styled fire-balls. From 7.30 to 8 he counted 309, from 8.30 to 9 there were 375, and from 9 to 9.30 there were 208. The sky then became cloudy. Not one can have reached the ground, for they must have burned out and dispersed in the upper atmosphere. At Munich the sky was perfectly clear, and the display was very striking.

THE LATE SIR WILLIAM SIEMENS

ON Thursday last the relations and friends of the late Sir William Siemens assembled in the Jerusalem Chamber of Westminster Abbey for the purpose of doing honour to his memory by the unveiling of a memorial window, which has been contributed by members of the five engineering Societies with which Sir W. Siemens was associated in the Abbey. The day was chosen as being the second anniversary of the funeral service which was held in the Abbey previously to the interment of the great *savant* at Kensal Green Cemetery.

Among those present were Mr. Arnold Siemens, Miss Gordon, Dr. Werner Siemens, and Mr. Alexander Siemens. Of the Civil Engineers Sir Frederick J. Bramwell, F.R.S., President, Sir Charles H. Gregory, K.C.M.G., Mr. Bateman, F.R.S., Mr. Barlow, F.R.S., Sir J. W. Bazalgette, C.B., Mr. Preece, F.R.S., Sir R. Rawlinson, C.B., and others, besides representatives of other Societies, among them Admiral Sir R. Spencer Robinson, K.C.B., Dr. Percy, F.R.S., Sir Bernhard Samuelson, Sir Henry Bessemer, F.R.S., Prof. W. G. Adams, Sir F. A. Abel, C.B., Prof. D. E. Hughes, F.R.S., Prof. Ayrton, F.R.S., and Dr. Hopkinson, F.R.S.

The Dean opened the proceedings by a brief address. "It is not for me," he said, "to dwell for a moment on the signal services to the cause, not only of science, but still more the application of science to the well-being of mankind, that will be always associated with the name of Sir W. Siemens. But I may add my own personal testimony to the impression which the character of your friend and leader, for such in a wide range of subjects I may surely call him, made on all who came into contact with him. He was, as you know, and as I know, not only admired and honoured, he was beloved and deplored. May the window which we shall now uncover do its proper work. . . . And may it remind us and far-off generations of the achievements and character of him whose memory will henceforth be here linked with that of his illustrious brethren, whose names the floor on which we shall soon stand, and the walls beneath which we shall pass, proclaim and preserve—the Newton, the Herschel, and the Darwin, the Stephenson, the Locke, and the Brunel, the Barry, to which add the Gilbert Scott, and Street—who sleep, or are honoured hard by."

Sir F. Bramwell, who spoke as the President of the Civil Engineers, the senior of the Societies represented, then made some remarks on Sir W. Siemens's contributions to applied and pure science.

The window, which has been designed and executed by Messrs. Clayton and Bell under the direction of Mr. J. L. Pearson, is intended to illustrate the maxim "Laborare est orare." It consists of two lights with a sixfoil in its traceried head. Each of these lights is composed of three panels in vertical order. In the left-hand light appear ironsmiths, chemists, and agriculturists; in the other groups in corresponding positions show astronomers, artists, and the professor with his scholars. Between these groups are in all cases angels bearing labels inscribed with the words giving the key-note of the conception—namely, "Laborare est orare." In the sixfoil at the head of the window is a representation of the sun as the source of light, surrounded by the words, "Dixit autem Deus fiant luminaria in firmamento cœli," and by the various heavenly bodies from which light emanates or is reflected. At the base is the following inscription:—"In memory of Charles William Siemens, Knt., D.C.L., LL.D., F.R.S., Civil Engineer. Born 4 April, 1823; died 19 November, 1883. Erected as a tribute of respect by his brother Engineers."

NOTES

It is gratifying to be able to announce that a pension of 300*l.* a year has been conferred upon Prof. Huxley from the Civil List Fund. We are also much pleased to notice the admirable articles in the *Times* and other papers on the retirement of Sir Joseph Hooker and Prof. Huxley, indicating, as they certainly do, the general growth of scientific interest.

We regret to learn of the death, in his 72nd year, of Prof. Thomas Andrews, F.R.S., the eminent chemist. We hope to be able to refer to his work in detail in our next number.

Botanists all the world over, we are sure, will be glad to learn that Mr. W. T. Thiselton Dyer, C.M.G., F.R.S., has been nominated to succeed Sir Joseph Hooker in the Directorship of Kew Gardens.

Our Paris Correspondent informs us of the death of M. Bouley, President of the Paris Academy of Sciences, who was to have held office until the first meeting of 1886. M. Bouley, who was born in Paris in 1814, died of heart disease, under which he had been labouring for many years. He was, during many years, Director of the Veterinary School of Alfort. He has published a large number of memoirs on physiological researches, and was a popular writer and an eloquent debater.

The reports of observations of the total eclipse of the sun of August 7, 1869, made by parties under the direction of Prof. Coffin, Superintendent of the *American Nautical Almanac*, have recently been published by the authority of the Secretary of the Navy. All lovers of astronomy will regret to know that this late publication in full of observations made sixteen years ago is due to the failing health and sickness of Prof. Coffin. This is, however, the less to be regretted since pretty full reports were made by the individual observers at the time, and the important observations secured have in this way found their place among the records of eclipse phenomena. The illustrations which accompany the volume are very beautiful.

We have received No. 15 of the professional papers of the Signal Service of the United States Army, containing a full account of Prof. Langley's researches on solar heat and its absorption by the earth's atmosphere, undertaken during, and in connection with, the Mount Whitney Expedition. Prof. Langley has already himself given an account in Nature of the important results he thus obtained. A perusal of the volume, however, shows that all who are interested in this subject will do well to refer to the present volume and the more detailed accounts they will find there touching the various parts of the research. It is a monument of industry and skill and undaunted perseverance of which Prof. Langley may well be proud.

The Christmas Lectures at the Royal Institution will be given by Prof. Dewar, on "The Story of a Meteorite" (with experimental illustrations), commencing on December 29. Courses of lectures will probably be given before Easter by Prof. R. S. Ball, Mr. R. S. Poole, Mr. C. T. Newton, Dr. A. Gamgee, Mr. W. C. Roberts-Austin, Prof. Boyd Dawkins, Prof. Tyndall, Mr. A. Geikie, Rev. C. Taylor, Mr. E. B. Poulton, and Mr. H. Grubb. The Friday Evening Meetings will begin on January 22, when a discourse will be given by Prof. Tyndall. Succeeding discourses will probably be given by Sir William Thomson, Mr. T. P. Teale, Prof. O. Reynolds, Mr. W. K. Parker, Mr. A. A. Common, Prof. A. Macalister, Mr. R. S. Poole, Mr. W. H. M. Christie, Mr. W. Anderson, Sir Henry Roscoe, and others.

The curriculum of the Paris School of Ethnology (founded by M. Broca in 1876) for the current session embraces courses of lectures on zoological, general, and prehistoric anthropology, ethnology, medical geography, and the history of civilisation. The course on linguistic anthropology does not commence until the spring. On zoological anthropology Dr. Duval will lecture on anthropogeny and comparative embryology: the blastoderm and the first phases of development. In general anthropology, Dr. Topinard will take type and race: the first part analytical—the races of Europe from prehistoric times down to our own days; the second part synthetical—the succession and transformation of races, their past and future. In ethnology, Dr. Dally will take ethnical craniology; in prehistoric anthropology, M. Mortillet takes Tertiary man; and in the history of civilisations, Dr. Lebourneau will lecture on the evolution and ethnography of morality.

We have received the price list of the publications of the Smithsonian Institution up to July last. It includes only such publications from 1847 to the present year as can be supplied, all others being out of print. The latter are very numerous, for of the first hundred publications only forty-six are now to be procured, the remaining sixty-four being out of print. The list first gives the papers according to their numbers in the publication catalogue of the Institution, then according to the authors, then according to their subjects, and finally they are arranged under heads according to their mode of publication, such as "Annual Reports," "Contributions to Knowledge," "Proceedings of Societies," &c.

Telephonic communication between Paris and Rheims was opened to the public on Tuesday. The distance is 172 kilometres, but the electric resistance to be overcome between the two points is estimated at 217 kilometres. The ordinary telegraphic wire is utilised for the purpose, but there is a special telephonic station in the Plain of St. Denis, at the Pont de Soissons. The tariff is one franc for five minutes' conversation. At the inaugural *séance*, conversations were held with sundry public functionaries at Rheims, whose voices were heard with perfect distinctness.

Prof. Du Bois-Reymond, it is known, has recently availed himself of good opportunities for studying the electric ray in the live state; and among several important facts elicited by him is that of irreciprocity of conduction in the electric organ. That is, when short currents are passed through the organ in the same direction as that of the animal's proper current, viz. from belly to back, and in the reverse direction, the conductivity in the former case is considerably greater. This irreciprocity begins to appear only when the current has acquired a certain strength; it increases with the strength, but more slowly. Both this irreciprocity and the small conductivity of the organ (which is considerably less than that of sea water) are proved to be connected with the life of the animal; the former disappears and the latter increases in the case of spontaneous death. The former depends also on the duration of the current, diminishing with a continuous current. This phenomenon of irreciprocity appears to have the effect of strengthening the animal's current and so intensifying its physiological action in external space. The author's researches on the subject have been recently laid before the Berlin Academy (*Sitzungsberichte*, Berlin Academy, 1885, p. 691).

The fresh-water mussel, it is known, closes its shell by contraction of two strong muscles—one before and one behind; but how does it open its shell? This question has recently been studied by Herr Pawlow (*Pflüger's Archiv*). The animal (*Anodonta cygnæa*) was fixed on a board by one shell, while the other free shell was connected by means of a silk thread with the short arm of a lever, the longer arm of which indicated the movements on a slowly-rotating drum. The nerves were variously irritated; but without giving details we may say that Herr Pawlow finds there are two classes of nerve-fibres connected with the muscles—the one motor, producing contractions; the other inhibitory, producing relaxation. The motor nerves for each muscle spring from the ganglion next it; the inhibitory fibres all proceed from the two front ganglions. The posterior ganglion can thus only send an impulse of movement to the posterior closing muscle, while the front ganglions, besides being thus related to the front muscle, can also produce relaxation in both muscles. When separated from the ganglions belonging to them the muscles pass but very slowly from the contracted to the relaxed state. A remarkable fact, noted by Herr Pawlow, is that by stimulation of the nerves in the muscles contraction does not always follow, but sometimes relaxation. Such phenomena are rare; they have been observed in the blood-vessels, and Herr Biedermann has noticed them in the heart of the snail.

The hatching of fish-ova has commenced at the establishment of the National Fish-Culture Association, South Kensington, several agents having been employed lately to artificially spawn fish, which in many parts are well forward. The species chiefly operated upon have been the *Salmo fario* and *S. levenensis*. The American Government have promised to forward large consignments of ova from the various species of Salmonidæ abounding in their waters, particularly the whitefish, whose eggs will be incubated in very large numbers by the Association.

The telegraph system of the Great Northern Telegraph Company has been extended to Seoul, the capital of Corea, and to its port, Jenchuan, or Chemulpo. These two places are therefore in telegraphic communication with the rest of the world.

A writer in the *North China Herald*, on ethnology in China, points out that while there have been geologists, botanists, and zoologists in China, no one has yet given himself specially to ethnology who was already distinguished in it. The province of Szechu'en is a very interesting and important region for the work of the ethnological geographer, because of the Thibetan tribes, the Lolos, and others located there. In the historical ethnology of China, De Guignes led the way in the last century in his "History of the Huns," which unfortunately were not the real Huns, for the Huns of Hungary were not, as he supposed, the powerful race known in China as the Hiung Nu. Yet he did much in elucidating the history of all the Tartar races, and his great merit was that he collected a large store of historic facts from Chinese sources, from the second century B.C., when the Chinese began to know Tartary, down to the days of the Mongol conquest. Klaproth settled the point who the Hiung Nu really were by the simple method of taking the words mentioned as theirs by Chinese authors, and finding out to what linguistic stock they belonged. Besides making this step forward, Klaproth also tabulated the facts of Chinese history relating to all Asiatic races.

What remains to be done for ethnology in the field of Chinese history is, the same writer adds, by no means a small amount of work. It is possible to trace the Indo-European races mentioned by ancient Chinese authors, and follow them in their movements westward, from Kansu to the Tsemgling mountains, and beyond, where at Bokhara and Kunduz they meet with other Indo-European stocks. In the north-west, besides these, Chinese history introduces us to several Indo-European peoples, occupying before the birth of Christ the country around the Sea of Aral, from which the Germanic races appear to have moved westward. The Chinese tell us nothing of the first emigrants, the Cimbri and Celts, but they give very considerable information about the Germanic races, the value of which has not yet been fully appreciated. Then the Huns, Avars, and Turks went forward, and the facts respecting them in Chinese history are, taken altogether, more abundant than upon any other foreign stock of nations. "Hence there is every inducement for the historical ethnologist to study Chinese history carefully."

Messrs. Macmillan and Co. will publish immediately a work on the "Elements of Thermal Chemistry," by Mr. M. M. Pattison Muir, assisted by Mr. D. M. Wilson. It is intended to present a connected account of the methods and results of the most important researches in the subject. Dealing rather with principles than with details, it is adapted for the use of students with a fair knowledge of the principles of Chemistry and the outlines of the study of Energy. The book is divided into two parts—the first devoted to the statement and consideration of the various branches of thermal chemistry; the second comprising most of the data on which the science is built. These data are classified and tabulated in five appendices, which it is hoped will prove of considerable service to students.

A NEW and thoroughly revised edition of Mr. H. B. Woodward's "Geology of England and Wales" is announced. The author has devoted nearly all his leisure hours since 1876 to the preparation of it, sparing no pains to render it as complete and accurate as possible. While giving prominence to the general description of the rocks, their leading fossils, and economic products, some details will be inserted to show the chief variations of the strata when traced across the country. Numerous tables and diagrams will also be given, to show the relations of the larger groups and of the local and minor divisions of each series of stratified rocks. The history of each rock-name, and its synonyms, so far as possible, will be briefly noted. The endeavour is made to explain every local rock-name, as well as the terms applied to particular beds or zones of fossils. The account of the geology of the principal lines of railway will be very much enlarged. The book will be published by subscription. Mr. Woodward's address is 7, Kelvin Terrace, Highbury Park, N.

THE additions to the Zoological Society's Gardens during the past week include a Levaillant's Cynictis (*Cynictis levaillanti* ♂) from South Africa, presented by Mr. W. Hope; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus* ♀), a Wedge-tailed Eagle (*Aquila audax*) from Australia, presented by Mr. G. T. Wills; a Cape Buffalo (*Bubalus caffer* ♂) from South Africa, presented by Mr. J. Gorton; two Cape-crowned Cranes (*Balearica chrysopelargus*) from South Africa, presented by His Excellency Sir Henry E. Bulwer, G.C.M.G.; a Goshawk (*Astur palumbarius*), European, presented by Mr. W. H. St. Quintin; an Indian Kite (*Milvus govinda*) from India, presented by Mrs. E. C. Mathews; a Cerastes Viper (*Vipera cerastes*) from Moses' Well, Arabia, presented by Lieut.-Col. G. W. Smith; two Moose (*Alces machlis* ♂ ♀) from Norway, a Blue and Yellow Macaw (*Ara ararauna*), a Red and Yellow Macaw (*Ara chloroptera*) from South America, four Gold Pheasants (*Thaumalea picta* ♂ ♂ ♀ ♀) from China, deposited; two Ring-tailed Lemurs (*Lemur catta* ♂ ♂) from Madagascar, two Aldrovandi's Skinks (*Plestiodon auratus*) from North-West Africa, purchased; three Lions (*Felis leo*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE DEARBORN OBSERVATORY.—Prof. Hough's report to the Directors of the Chicago Astronomical Society is as usual chiefly occupied with the observations of Jupiter which have been made with the great refractor. The great red spot still forms, of course, the object of greatest interest. The curious filling up which it underwent last February, whereby for a time it presented the appearance of a reddish elliptical ring, with a white centre, is described, and also its gradual return to its normal appearance. The red spot has now been watched for seven years, and during that time its latitude, shape, and size have undergone but little change. The length, however, appears to have diminished slightly in 1884 as compared with 1883, Prof. Hough's measurements being 12"·29 for 1883, and 11"·26 for 1884. The breadth, on the other hand, seems somewhat greater, so that it is less markedly elliptical than in former years. The mean rotation period for the interval 1884 September 25 to 1885 June 29 was found to be 9h. 55m. 40·4s., or somewhat greater than in previous years. "The depression in the equatorial belt under the red spot, which was formed in 1882, has continued, but is gradually being obliterated." "The principal equatorial white spot which has been observed since 1879 was not so conspicuous as in former years." The old rotation value, 9h. 50m. 9·8s., satisfied the observations.

Of other observations the principal recorded are the discovery of thirty-nine new double stars, an observation of the companion to Sirius, 1885·195, Dist. = 7"·96, Posn. Angle = 32°·7, and a series of photographs of the sun taken during the partial eclipse of 1885 March 16. Prof. Hough describes a printing chronograph which he has had constructed, and which records at once the time of an observation to the hundredth of a second, and obviates the labour now necessary to convert the ordinary chronographic record into numbers. He estimates the pecuniary value of this labour in a first-class observatory as at least 200*l.* annually.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, DECEMBER 6–12

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 6

Sun rises, 7h. 53m.; souths, 11h. 51m. 22·3s.; sets, 15h. 50m.; decl. on meridian, 22° 34′ S.: Sidereal Time at Sunset, 20h. 52m.

Moon (New) rises, 7h. 18m.; souths, 11h. 51m.; sets, 16h. 21m.; decl. on meridian, 17° 34′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury	9 36	13 18	17 0	24 55 S.
Venus	11 16	15 17	19 18	22 12 S.
Mars	23 11*	6 0	12 49	8 48 N.
Jupiter	1 8	7 12	13 16	0 5 S.
Saturn	17 19*	1 28	9 37	22 25 N.

* Indicates that the rising is that of the preceding day.

Meteor Showers

The two principal showers of this week are the Taurids II., radiant R.A. 80°, Decl. 23° N., near ζ Tauri; and the Geminids, radiant near α Geminorum; the former should be specially looked for on December 6, the latter December 9-12. Fire-balls have frequently been seen during the latter period. Another shower from Taurus, R.A. 56°, Decl. 6° N., near ν Tauri; and another from Gemini, R.A. 108°, Decl. 20° N., near ζ Geminorum, have also been sometimes observed during this week.

Objects with Remarkable Spectra

257 Schj.—R.A. 21h. 50m. 58s., Decl. 49° 57'·2 N. Mag. 9·1 Secchi's fourth type. The dark band in the yellow is abnormally broad.

19 Piscium.—R.A. 23h. 40m. 31s., Decl. 2° 51'·0 N. Mag. 6·2. One of the finest examples of the fourth type of spectrum.

Mr. Marth has called attention to the following conjunction of Saturn with DM. 22° 1383, which should be watched, as it may possibly prove to be an occultation:—

	h.			
Dec. 9 ...	16·4	✳ ☌	with *p* edge of ring,	$y = -\ 8''\cdot0$
	18·4	✳ ☌	with centre of Saturn,	$y = -12\cdot2$
	20·5	✳ ☌	with *f* edge of ring,	$y = -16\cdot4$

The magnitude of the star is 8·7.

GEOGRAPHICAL NOTES

THE *Invalide Russe* publishes the following telegram from Col. Prjevalsky from Pishpek, but dated Karakol, 2nd (N.S. 14th) November:—"Our voyage has ended happily, and with the most encouraging scientific results."

AT the meeting of the Paris Geographical Society on the 20th ult., M. Alphonse Milne-Edwards in the chair, the return of M. de Brazza was announced, as well as his promise to read a paper before the Society on his journeys in the Congo. The President also reported the return of M. Aubry from more than two years' exploration in Choa and part of the country of the Gallas, Danakils, and Somalis. During that time he determined the course of the Haouach River and its affluents, the Mongueur, Goudredet, and Ganjad, as well as the heights of various mountains. He was also able to make numerous observations on the geology, palæontology, and mineralogy of the region. M. Duveyrier stated that the altitude of Fez, which has never before been determined, is about to be calculated by M. Feraud, by the barometer, to within 10 metres. He has found it necessary to make no fewer than 127 observations in order to obtain this result. M. Coudreau referred to the latest stage of the dispute between France and Brazil with regard to the territory lying between French Guiana and Para.

THE *Bulletin* (1885, No. 5) of the Belgian Society of Geography contains a long paper by M. Leclercq on Mexico, which is really a translation and *résumé* of a recent Mexican publication. The present paper is arranged under the following heads:—Situation and boundaries, institutions, political divisions and population, ethnography, with an approximate census of the Indian tribes, industries, railways, and other methods of communication, orography, climate, and productions. It is thus, it will be perceived, a tolerably complete account of the Mexican States.

THE *Boletin* of the Geographical Society of Madrid for October (vol. xix. No. 4), is, as might be expected, mainly occupied with the Caroline Island question. The only map attached to the number is one of the Western Pacific from the Philippines on the west and New Guinea on the south, including the Pelew, Caroline, Marshall, Gilbert, and Ladrone or Marianne groups. The first contribution is a letter from the Society by its authorised officers to the Government on the question, and claiming the islands as belonging historically to Spain.

IT is stated that an accurate survey of the Island of Yezo, and the neighbouring islands (especially the Kuriles), is to be made by the Japanese Naval Department. It is anticipated that the work will occupy four years.

AN Exhibition of Appliances used in Geographical Education in England and on the Continent will be opened by the Royal Geographical Society at 53, Great Marlborough Street, on December 9, and will remain open till January 31.

THE latest numbers of the *Verhandlungen* of the Berlin Geographical Society (Band xii. Nos. 7 and 8) contain papers by Dr. Penck, on the mountain systems of Central Germany; and by Dr. Schulz, on a journey from Port Natal to the Kalahari, and especially the exploration of the Rivers Chobe and Cubango. Dr. Rath (in No. 8) contributes a geographico-geological study of the Pacific regions of North America, and the substance of a lecture by Dr. Buchner on the Cameroons is also given.

A CORRESPONDENT with General Scratchley in New Guinea reports that Mr. H. O. Forbes is going to attempt to reach the summit of Mount Owen Stanley, 13,205 feet high, and hitherto untrodden by the foot of man. Mr. Forbes will form a depôt camp at Sogeri, 25 miles inland, and survey, collect specimens, &c., in the neighbourhood of the lower ranges. Next spring, when the weather will be suitable, he will make the attempt to climb to the highest point. He may, the correspondent says, spend several years in New Guinea, for his wife is following him, and his heart is thoroughly in his work.

THE Swedish Society of Anthropology and Geography has commissioned Baron Schwerin, Professor of Geography at the University of Lund, to proceed on a scientific expedition to the Congo, the chief objects being to make geographical, meteorological, botanical, and zoological studies in the new State, and to collect ethnographical objects. Barons Nordenskjöld and Dickson have lent the Expedition a number of valuable instruments. The Swedish Government have requested Prof. Schwerin to report on the commercial opportunities afforded on the Congo and the position of Scandinavian subjects there.

EXPLOSIONS IN COAL MINES[1]

THE address to which the members of the Society of Arts were so good as to afford a favourable reception at the opening meeting of last Session, was in great measure devoted to topics suggested by the International Health Exhibition of that year. Wide as was the scope of that Exhibition, which dealt not only with the necessaries and comforts of life, and the promotion of bodily health in the feeding, clothing, and housing of all classes, but also with the all-important subjects of physical and mental training, the Exhibition of Inventions—which has just terminated a prosperous and, I believe, a very useful career—embraced a wealth of material for study which could bear comparison, as regards extent and interest, with that presented by any one of the great International Exhibitions of former years, the initiation of which we owe to that illustrious Prince whose memory the Society of Arts delights to honour.

I have resisted the temptation to devote this evening to a brief review of some of the chief matters of interest presented by the most prominent sections of the Exhibition, because I entertain a lively hope that a thorough examination of at any rate *many* of these will afford topics for important communications to this Society, and I consequently feel that it would be scarcely just to those who may consent to devote themselves to their preparation, were I to cull specially attractive matter from the mass of information opened up to the student by the achievements demonstrated at the Exhibition. I therefore propose to limit myself in this address to the treatment of some matters relating to only one branch of a division of the Exhibition, namely, the class which deals with machinery and appliances *used in mines*.

I venture to think that this class of subjects has claims to special interest, *because* the mining industry ranks among the most important sources of the wealth and cosmopolitan influence of the Empire; *because* its development and successful pursuit have involved the utilisation of the resources of many branches of applied science, and have taxed the talents and ingenuity of some of our greatest mechanics, and most accomplished physicists and chemists; and, though last, not least, *because* the pursuit entails the encountering of dangers and vicissitudes which will aptly bear comparison with those involved in the careers of the soldier and the sailor. Thrilling and harrowing accounts of great disasters in coal mines direct public attention from time to time to certain special dangers which the miner has to encounter, but the annual reports of H.M. Inspectors of Mines show that there are yet others to which miners in general are daily exposed, which, although they do not attract public attention (partly because of the very circumstance of their constant occurrence, and partly because the sufferers by them meet their deaths in most cases

[1] Address of Sir Frederick Abel, Chairman of Council of the Society of Arts, delivered at the opening meeting, Nov. 18, 1885.—(Abstract by the Author.)

singly), are nevertheless far more formidable in regard to the gross extent of the fatalities attending them, than are coal-mine explosions.

When the late Mr. MacDonald, M.P. for Stafford, made his remarkable speech in the House of Commons, in 1878, advocating the necessity for the more rigorous inspection of coal mines, and supported his arguments with the enumeration of an appalling list of disastrous colliery explosions, it was pointed out by Mr. Thomas Burt, and other members, that explosions did *not* constitute the chief element of danger which the miner had to encounter, and that, while out of 25,000 lives which had been lost in mines since 1851, over 6,000 deaths had been caused by explosions, there were more than 10,000 due to falls of stone and coal in the mine workings, which attracted little or no public attention. Mr. Cowen also pointed out that there was a still larger number of injuries, due to such causes as these, which were never heard of beyond the locality of the disasters, because they were not attended with fatal results at the time, although in the larger proportion of such cases the sufferers were either maimed for life, or died after more or less brief intervals. The Table below, which has been compiled from the annual reports of the Mine Inspectors for the past ten years, shows the total number of deaths annually due to accidents in mines, and the deaths due respectively to explosions, to the falls of roof or sides in mine workings, and to other miscellaneous causes; and it will be seen that even in those years when especially disastrous explosions had occured, the fatalities due to explosions were, with the exception of two years, considerably in the minority, compared with deaths from falls of roof and sides, while—comparing them with the deaths due to all other causes—the latter were invariably much in excess. It is not surprising, however, that the paralysing moral effect exercised upon small mining communities, and the heartrending local misery and suffering which suddenly and simultaneously fall upon many families, should cause coal-mine explosions to command special sympathy, and to call forth public expressions of regret and surprise that the resources of science and of legislative power should have failed utterly to prevent, or even very greatly diminish, such sad disasters, while, on the other hand, the daily occurrence of fatal accidents in the ordinary pursuit of the miner's vocation, attracts little public attention. It has been contended that the classes of constantly recurring accidents, which combine to cause a far more formidable

STATEMENT OF PROPORTION, AT COLUMN II., OF DEATHS FROM EXPLOSIONS IN COAL MINES, FROM FALLS OF ROOF AND SIDES, AND FROM OTHER MISCELLANEOUS CAUSES, TO TOTAL DEATHS IN MINES FROM ALL CAUSES DURING THE YEARS 1875–1884[1]

Year.	Total Number of Deaths from Accidents of all kinds.	No. of Deaths from: Explo-ions of Fire-damp.	Roof and Sides falling.	Other causes.	Results of some of the more disastrous Explosions in each year.

[1] The facts embodied in the above Table have been long accessible to all who care to inform themselves correctly, by reference to the published annual reports of H. M. Mine Inspectors; it is, therefore, somewhat surprising to find that the Manchester Correspondent of the *Times*, to whose views that journal appears to attach much weight, and whose evident acquaintance with high authorities in matters relating to coal mines, such as Mr. Ellis Lever, should have, at any rate, assisted him to a knowledge of the existence of those reports, is ignorant of the truth relating to a subject with which he deals in a fashion somewhat over-authoritative for the representative of "unenlightened earnestness," which is "impatient" to learn the reason for "hesitation" on the part of a Royal Commission on mine accidents in promulgating its conclusions, is "incredulous of the difficulty of speaking out," and indignantly regards "the delay as a national scandal." In support of this somewhat strong expression of sentiment, "unenlightened earnestness" inquires whether it has "really needed so long to dispel any doubt that shot-firing, for instance, is the commonest cause of the loss of life in coal mines."

total of deaths than even an unusual succession of serious explosions, are to a great extent made up of unavoidable sources of danger to which the miner must be exposed; and that, on the other hand, the causes which lead to explosions have been long known, and can be readily grappled with and removed by the colliery owner or manager. But as a matter of fact the nature of some of the chief and most prevalent conditions favourable to mine explosions is only now being thoroughly made clear, and the same may be said of the nature of measures and appliances by which explosions may be avoided or diminished in magnitude.

From the foregoing considerations, it is evident that very great interest and importance must attach to any decided improvements in systems of working, or in appliances connected with mining, and bearing directly upon the safety, facility, and degree of comfort, with which subterranean operations can be carried on. The members of the Society of Arts will, therefore, I feel sure, take a lively and sympathetic interest in the statements and observations which I have to offer in connection with the Mining Section of the late Exhibition, and, in reference to the labours, now fast drawing to a close, of a Commission, appointed by Her Majesty about six and a half years ago, to inquire and report whether the resources of science could furnish any practical expedients, not then in use, calculated to prevent the occurrence of accidents in mines, or to limit their disastrous consequences; a Royal Commission whose earnest and disinterested labours have been patiently, steadily, and faithfully pursued to successful issues, in spite of engrossing official public and professional duties, and undeterred by the public censure and abuse with which the persevering efforts of its members to complete, as far as practicable, the heavy task allotted to them, have as yet been alone encouraged.

The display at the recent Exhibition of implements and appliances connected with mining, was sufficiently comprehensive to be fairly representative of the nature of improvements which have of late been accomplished in almost all directions. Some of the exhibits demonstrated very important progress made since the Accidents in Mines Commissioners commenced their labours, and are traceable in several instances to certain results of those labours, which, though not formally communicated to the public, have become known to many engaged in the management and supervision of mines.

An examination of the evidence taken by the Commission, and published with their Preliminary Report, showed that there were several important subjects connected with the safe and efficient working of mines upon which large differences of opinion prevailed. This was especially the case with reference to the employment of naked lights in mines—the relative merits of well-known safety lamps—the uses of gunpowder or other explosives underground—and the possible influence of coal-dust in the development or extension of explosions. It was, therefore, especially in these directions that the Commissioners considered it their paramount duty to pursue experimental inquiries, and, as those investigations proceeded, their importance and the useful results likely to emanate from them became the more apparent, while each succeeding step demonstrated the necessity for proceeding further in the inquiries, so that, even up to this, the period fixed by them for the completion of their final Report, the Commissioners have found themselves still engrossed in experiment.

Without presuming to deal in anticipation with the conclusions arrived at by my colleagues and myself as the results of our protracted investigation, I may venture to indicate the nature of some of those results sufficiently to illustrate the progress made in certain matters most vitally affecting the safety of the miner.

The important advances which have of late been made in the methods of operation, and mechanical appliances, provided for exploring and for breaking ground, were illustrated in the Exhibition by some of the most recent improvements in boring and drilling machines, and in the construction of the more ordinary hand tools. Without dwelling upon the marked advance which has been made in the operations of deep-boring and of tunnel-driving, by combining the utilisation of steam or compressed air with the method of continuous flushing, special reference must be made to the great improvement effected in mining operations by the use of drills or perforators driven by compressed air, of which several varieties were shown at South Kensington.

So-called coal-cutting machines, for holing or undercutting coal, of which many forms have constituted prominent features in the mining sections of former Exhibitions, were only represented by one variety on the present occasion, and appear to have hitherto made little way, although their use would seem to be attended with some decided advantages. Hydraulic pressure has been applied with some degree of success in connection with drilling machines and with the forcing down of coal; thus, Messrs. Dubois and François have applied a very efficient hydraulic arrangement, called the *Bossoyeuse*, with considerable practical success, to the removal of rock or stone in mines where fire-damp exists. As regards the different methods of working seams of coal, and the variety of circumstances which determine their expediency or relative merits in different cases, I must limit myself to the statement that the so-called *long wall* system, which consists in the continuous excavation of the coal throughout or along a considerable distance of the breadth of the seam, the excavated part being filled up, as the work advances, with stone and slack, or with material brought from the surface, presents facilities for securing efficient ventilation, and other advantages in regard especially to the safety of the workmen, by which it recommends itself for choice wherever it is applicable, and which, supplemented by the employment of wedges, have been used successfully for bringing down coal or rock in some localities where fire-damp is prevalent.

Large as is the proportion which accidents arising from falls of roof and sides in mine-workings bear to casualties of all other descriptions, an examination of the Mine Inspectors' Casualty Returns happily shows that a considerable improvement has actually taken place in the death-rate from falls during the last twenty years. This is unquestionably owing to bestowal of increased care upon the proper support, by timbering or arching, of the roof and sides of many workings, or upon improvements in the system upon which this most important work is carried out. Cheering as these results are, it cannot be doubted that much remains to be accomplished in order to reduce the proportion of casualties from these causes to some approach towards what might be reasonably accepted as unavoidable at the present day.

One great safeguard to the miner against accidents from falls of stone and coal would obviously be the provision of efficient illumination of the ways and working places. A powerful excuse for the use of naked lights, even where risk of producing explosions was known to be incurred thereby, has been sought, and even sometimes admitted, in the necessity for more light in insecure places than that furnished by the Davy, the Geordie, or the Clanny lamp; the argument against enforcing the general adoption of safety lamps, most strongly urged by Mr. Burt and others in the debate of 1878, was the miserable insufficiency of the light afforded by them, and the consequent increase in the number of accidents due to causes other than explosions. Among improvements of late effected in the construction of safety lamps, has been the increase of their illuminating power; and this subject of underground illumination is, I may confidently say, ripe for very great amelioration.

The simple modes of underground transport of coal by manual or horse labour have now, to a very considerable extent, given place to its haulage, along tramways, by means of wire ropes or chains actuated either by steam hauling engines placed near the pit bottom, or by compressed air-engines stationed in different parts of the main roads. Some good illustrations of hauling machinery of these kinds were included in the Exhibition, and members of the Society of Arts cannot fail to remember with interest that our late lamented chairman, Sir William Siemens, was the pioneer in the introduction of electric hauling arrangements for mining work.

A fruitful source of disaster connected with mines has been the descent or ascent of the men by the shafts, and many contrivances have been devised, and more or less extensively applied, for preventing accidents resulting from the overwinding of the cages in which the men and the coal are brought to the surface, or from the fracture of the rope with which these cages are worked.

Really efficient and trustworthy appliances of this class cannot fail to be important safeguards, equally perhaps with those afforded by great improvements which have been effected in the construction and quality of the hauling- or pit-ropes. It is impossible to overrate the necessity for the bestowal of the highest skill and care upon the manufacture, testing, and periodical inspection of these all-important adjuncts to mining work, to which many thousands have daily, in blind confidence, to trust their lives.

The great improvements which have been effected in the steam brakes and reversing gear applied to the powerful winding-engines which, as monuments of mechanical skill, merit the careful inspection of all interested in mining industry, are most important additions to the safety appliances provided in the present day in connection with the pit work of our mines. To these must be added the improvements made in signalling arrangements from the surface and underground, in connection with which electricity has of late commenced to play an important part.

The great advance made in the *ventilation* of mines during the past half century is well known to all who have paid the least attention to these matters. Not only has the ventilating furnace been greatly improved in efficiency and power; the steam jet and compressed air have received important application within the last thirty-six years, and fans, and other mechanical ventilating agents of great power have come into extensive use during the past twenty-three years.

The proper distribution of the air which is drawn down into the pit, and the arrangements necessary for insuring the distribution of fresh air throughout the different roadways and workings in a mine, and its isolation from return- or foul air-currents which are passing to the upcast or exit shaft, are now carried out effectually in a large proportion of our coal mines.

Although we have long been familiar with the nature of fire-damp, and with the generally-accepted explanation of its origin in coal, considerable uncertainty and consequent diversity of opinion still prevail as to the condition in which the gas is pent up in coal, and in the associated strata. That the light carburetted hydrogen, which chiefly composes fire-damp, exists, with its associated gases, in a more or less condensed condition, in coal, even some time after removal from the pit; and, that the gradual escape of the condensed inflammable gas from coal has constituted a fruitful source of disaster to coal-laden ships, and to steam-vessels carrying a large provision of coal—such as our ships of war—are very well known facts; but, there are constantly-recurring phenomena connected with the escape of gas from coal, a really satisfactory explanation of which is still wanting, although patient inquiry has long been devoted to its discovery. Thus it has been demonstrated by experiment that, if cavities are bored into the coal and plugged, the gas will speedily accumulate so as to exercise a pressure of several hundred pounds upon the square inch, as indicated by pressure-gauges fixed into the cavities.

In some localities, the gas issues as a jet, or so-called "blower," and many of these furnish a continuous supply of gas under fairly uniform pressure, which may be conducted in a steady stream to the surface, and utilised for heating and even for illuminating purposes. Many explanations have been offered of the existence of these blowers, and of the maintenance and sudden cessation of the gas supply, but they have remained a mystery.

The systems of ventilation now in use in coal mines, and the powerful circulation of air maintained thereby, deal effectually with the removal of gas, as it exudes from *freshly-worked* coal even in very fiery mines, when it passes into the main ways and the workings which are actually in use; but, in *old workings*, recesses, or cavities, and in the so-called goaves, where the worked-out space has been filled up with stone and *débris*, the gas may lurk and lodge, and may at any time constitute a source of great danger, if special means are not adopted to favour its removal; and, even with the most efficient and searching ventilating arrangements, the almost unavoidable existence of some accumulations here and there in mines where fire-damp is prevalent, renders absolute freedom from it, of the air in the mine, practically unattainable in such cases, although the amount diffused through the atmosphere may seldom, under ordinary conditions, approach, even distantly, to the minimum proportion which, *per se*, might constitute a source of danger.

It is now generally admitted that variations of atmospheric pressure influence the tendency of fire-damp to escape from goaves or old workings in a mine where accumulations are liable to exist, and that when a reduction of pressure suddenly sets in, such an escape may take place even to some considerable extent before the barometer indicates the depression. Some even maintain that the emission of gas from the fresh face of coal is considerably promoted by such alterations of pressure; but although there are many undoubted instances of explosions having occurred during sudden and very considerable depressions of the barometer, different observers in this and other countries are by no means in accord as to the extent to which, in a properly-ventilated mine, the existence of fire-damp in the air is influenced by barometric changes.

There are some mines so free from fire-damp that naked lights may be used therein with perfect safety, and others where the use of safety lamps need apparently be only insisted upon in certain parts of the workings. There can be no doubt, on the other hand, that the adoption of even the most perfect ventilation cannot secure such absolute safety as to render the use of naked lights warrantable, where seams are worked in which fire-damp exists in any abundance,—because danger may there arise at any time, from some accidental stoppage or partial failure of the ventilating arrangements, from the effect of a reduction of atmospheric pressure in promoting the escape of gas from lurking places, or, from a liability to the sudden emission of gas in considerable quantity from coal. The very poor light furnished by the forms of safety lamp still chiefly in use, has afforded very strong temptation to the men to have recourse to naked lights, and to the managers of mines to regard such proceeding with indulgence, even where its danger is well recognised. Poor as the light is which the older forms of lamps furnish in a quiet atmosphere, it becomes even much worse when they are exposed to such currents as are now met with in properly ventilated mines.

Efficient lamps should therefore burn brightly and steadily even in strong currents of air, and they should be unable, under any circumstances at all likely to arise in coal mines, to ignite an inflammable mixture of fire-damp and air, even when this is passing at the highest velocities which can occur in any part of a mine.

The importance of determining how far modifications of existing lamps, or new kinds, fulfil these conditions, has led individuals specially interested in the subject, and associations of mining engineers, for many years past, to submit lamps to comparative experimental tests; and the first branch of inquiry which was taken up by the Royal Commission was the systematic comparison of the behaviour of different lamps under variously modified conditions in currents of explosive mixtures of gas and air, travelling at different and accurately-determined velocities.

As the experiments proceeded, and the results of tests applied to particular lamps became known to the makers, modifications in construction were introduced, or new arrangements devised. More than 200 lamps have been submitted to a variety of trials, and even up to the present day the Commission have continued to receive new lamps, with urgent requests that they should be included in the trials.

This investigation has also included a careful determination of the amount of light furnished, and of the burning qualities of all the more promising lamps, as well as an examination into their practical merits, in regard to construction, weight, and handiness.

The results of these extensive investigations will now very shortly be in the hands of the public: I must content myself with very briefly indicating their general nature.

Only three types of lamp were until recently in extensive use in this country: the original safety lamps, which the miners owe to the genius of Davy and of Stephenson, and a lamp not long afterwards devised by Dr. Clanny. When the safety lamp was first invented, the ventilating currents in mines were very moderate indeed, and under the then prevailing conditions these earliest lamps were fairly safe. But, at the present time, the air in the mine roadways often travels at a rate of 20 to 25 feet per second, and may even, in some special places, attain velocities of 30 to 35 feet. Under these conditions the Davy and Clanny lamps cease to afford any security in localities where fire-damp is prevalent. This had already been indicated by the results of previous experiments when the Commissioners commenced their work, but their own investigation so clearly established the great danger of these lamps, and the facts already known on the subject appeared to have received so little consideration, that the Commissioners regarded it as their imperative duty to direct the Home Secretary's attention officially and in strong terms to the fact, in the hope that most prominent publicity would be at once given to their warning.

After some delay, a circular embodying the substance of it was issued, but without any indication that it bore the authority of the Royal Commission. This action was taken not long after the appointment of the Commission, yet the Davy and Clanny lamps have continued in use in mines where the elements of danger insisted upon exist.

The Davy lamp had, some years back, been rendered much less dangerous by the addition of a metal shield partially surrounding the gauze cylinder, or by the provision of an external glass cylinder extending up the gauze to various distances. The latter modification proved to be the most efficient safeguard of the two; but a much more important protection has been comparatively recently effected by inclosing the lamp in a case, which protects it to a great extent from the action of currents, though this considerably diminishes the already very meagre light afforded by this lamp.

A lamp of Belgian origin, termed the *Mueseler*, and which has for many years past been officially adopted in Belgian mines, presents important advantages over the lamps already referred to, which were, in part, recognised before the Commission existed, the lamp having since come into somewhat extensive use. Some experiments and certain results of practical experience had, however, already thrown doubt upon the wisdom of placing absolute reliance in the safety of this lamp; the Commissioners' experiments confirmed the validity of those doubts, and showed that, under particular conditions, the Mueseler lamp might cause an explosion when exposed to a current of fire-damp mixture of very moderate velocity. On the other hand, the *cased Davy* lamp was found perfectly safe, under much more severe conditions, and this important fact has led to the adaptation of cases in various ways to the old types of safety lamps—many so-called new safety lamps consisting, in fact, of the Davy and Clanny protected by inclosure from the direct action of the current.

The publication of the Commissioners' investigations will, I venture to affirm, convince even those who, although they have not cared to inform themselves of the character and extent of the work which was being done, have thought it right and just to publicly reproach the Commission with dilatoriness, that the curtailment of these researches would only have been detrimental to the conclusive, and therefore practically important, nature of the results arrived at. For, these have not only led to decisive conclusions regarding the defects of the best known types of lamps, and the degree of safety and other merits of a large variety of modifications of them, as well as of new forms of lamps, but they will also enable the Commissioners to indicate, with confidence, several lamps which combine a great degree of safety with other important merits, and to specify a few among these which, while ranking highest in point of safety, and leaving very little indeed to be desired in this respect, combine, with this first essential, the important adjuncts of simplicity of construction and fair illuminating power. It will, moreover, be possible to indicate some directions in which even these lamps are susceptible of improvement. It, therefore, only remains to be hoped that the results of the labour which the Commissioners have devoted to this branch of their inquiry will be accepted wtth the confidence they merit, and will be speedily utilised both by those who are responsible for the management of mines and by those who control the actions of the miner.

When the Commission's investigations were already considerably advanced, Mr. Ellis Lever publicly offered a premium of £500 for a miners' safety lamp, which, while being of convenient size for carrying about, would continue to give a useful amount of light for not less than twelve hours, *and which would not cause an explosion of gas under any circumstances at all likely to represent conditions which may occur in actual practice.* It was proposed that the judges to whom lamps submitted for competition were to be referred should include three scientists, nominated respectively by Mr. Lever, by the Royal Society, and by the Society of Arts. No less than 108 different lamps were sent in, and it need scarcely be said that the determination whether any among them fulfilled the prescribed conditions involved a very extensive series of experiments. The adjudicators who had to investigate the merits of the various lamps, included three scientists, and two were members of the Commission, who cheerfully consented to take upon themselves this very considerable addition to the voluntary labours already being carried on by them in the interests of the miners.

Only four electric lamps were submitted, and these altogether failed in fulfilling any one of the conditions laid down, excepting that of being self-contained lamps. Eventually, not one of the other lamps was found completely to fulfil the whole of the conditions under which the premium was offered, although several ranked very high as regards safety and efficiency; foremost among these being the lamp of M. Marsaut and that of Mr. N. Morgan, of Pontypridd, to whom gold medals have been awarded at the Inventions Exhibition, and whose lamps rank among those which the Commissioners are able to speak most highly of. But, the premium which Mr. Lever placed at the disposal of the adjudicators reverted to him, and those who have great experience of the behaviour of safety lamps of the various well-known and recently developed types, could scarcely have anticipated a different result. Mr. Lever has, since then, again offered a similar premium, this time for "the invention or discovery of an economical, efficient, and safe substitute for gunpowder and other dangerous explosives used in the getting of coal." The Council of the Society of Arts could not see their way to comply with the suggestions of Mr. Lever that they should award this premium, or appoint adjudicators for that purpose, as they did not feel themselves warranted in suggesting the great sacrifice of time, in the performance of the very laborious and exhaustive experiments indispensable in this case, to such as would be really competent to perform the work of adjudication, which Mr. Lever appears to think at least as lightly of as of the offer of these prizes. It borders upon the amusing to observe in the article by the Manchester Correspondent of the *Times*, to which such prominence was given on the 27th of last June, how the writer heralds offers of subscriptions and of premiums, as illustrating the way in which his hero "gallantly attacks the problem (of accidents in mines) at all points," while he has no encouraging word for the man of science whose disinterested devotion to very arduous work, for which his sole probable recognition would be hostile criticism, or worse, can alone give any point to the "gallant attacks" of philanthropists like Mr. Ellis Lever.

(*To be continued.*)

THE ROYAL SOCIETY[1]

AT the earliest opportunity after my return to England last spring I offered my very grateful acknowledgments to the Society for the kindness with which the Fellows had condoned my enforced absence from my post during the winter. And I should not venture to occupy your time by recurring to the subject, did not the return of St. Andrew's Day admonish me that duty and inclination alike require me to offer my especial thanks to the Treasurer for the cheerful readiness with which he took upon himself the burden of my duties, and the efficiency with which he discharged them on our last Anniversary.

On the last occasion on which I had the honour to address you, it was my painful duty to commence by lamenting the death of a very eminent member of the Society, who was, at the same time, one of my oldest and most intimate friends. I deeply regret to find myself once more in this position. The lamentable accident which has deprived the Society of one of its oldest and most distinguished Fellows, Dr. Carpenter, has robbed me of a friend, whose kindly sympathy and help were invaluable to me five-and-thirty years ago, and who has never failed me since.

You are all acquainted with Dr. Carpenter's great and long-continued services to science as an investigator and as an expositor of remarkable literary skill; and there must be many here who, having worked with him in the University of London, of which he was so long Registrar, are familiar with the high integrity, the energy, and the knowledge, which marked him as an administrator. He was a man of varied accomplishments outside the province of science, single-minded in aim, stainless in life, respected by all with whom he came in contact.

Within the last few days, Physics has lost an eminent representative in Dr. Thomas Andrews, of Belfast. Among the cultivators of Chemical Science we have to regret the decease of Mr. Field, who was one of the original members of the Chemical Society; of Mr. Weldon, and of Dr. Voelcker, whose names are well known in connexion with manufacturing and agricultural chemistry. In Biology, we have lost Dr. Davidson, whose elaborate monographs on the fossil Brachiopoda are remarkable examples of accurate malacological work combined with artistic skill; Dr. Gwyn Jeffries, the veteran explorer of our marine molluscous fauna, and a high authority on conchology; and Dr. Morrison Watson, whose early death has cut short the career of an anatomist of much promise. Mineralogy has suffered a similar loss by the premature death of Dr. Walter Flight. In Engineering Science, we have to lament the deaths of Mr. Barlow and Professor Fleeming Jenkin. I may be permitted to dwell for a moment upon the latter name, as that of a most genial and accomplished man and a valued personal

[1] Address of the President, Prof. T. H. Huxley, delivered at the Anniversary Meeting, November 30, 1885.

friend, with whom it had been my privilege to be associated for a time in his well-directed and successful efforts to improve the sanitary condition of our cities. The elder generation of English geologists will remember the keen interest which the Earl of Selkirk took in their pursuits. The death of Lord Houghton robs us of a connecting link with all the world.

Three very distinguished names have disappeared from the ranks of our Foreign Members: that of Henle, of Göttingen, among whose many merits must stand that of ranking next after Schwann among the founders of histology; that of the venerable Henry Milne-Edwards, of Paris, one of the most distinguished members of the school of Cuvier, and admirable no less for his contributions to zoological philosophy than for the extent and the precision of his additions to our knowledge of facts; and lastly, that of Von Siebold, of Münich, whose remarkable investigations into the phenomena of parasitism and of sexless reproduction brought about the solution of some of the most difficult problems of zoology, while it would be difficult to exaggerate the influence of his wonderfully accurate and comprehensive "Handbook" on the progress of invertebrate zoology forty years ago.

On the 1st of December last year the total number of Fellows of the Royal Society amounted to 519; of these 473 were on the home and 46 on the foreign list. Deducting Her Majesty, our Patron, and four other Royal personages, the number on the home list was 468. At the present moment, we have 49 foreign members, or within one of our full complement; while the total strength of the home list (deducting Royal personages) is 466, or two fewer than twelve months ago. The number of deaths in the home list during the past year is 20. This is a larger mortality than that of last year; and it still exceeds the number of Fellows added to the Society by election, which during the last part of the year was 16: namely, the statutory 15 Fellows elected in the ordinary way and 1 Privy Councillor.

As the Treasurer observed in his address on the last Anniversary, it is obvious that we are rapidly approaching a state of equilibrium between our losses and our gains; and, under the present conditions of election, the strength of the home list may be expected to remain somewhere between 460 and 470.

While our number thus tends to remain stationary, the list of candidates for the Fellowship, though it has fluctuated a good deal from year to year, has on the whole become longer, until, at present, the candidates are more than four times as numerous as the annual elections sanctioned by our rules. This state of things has given rise to comment, both within and without the Society, on more than one occasion. It has been said that any restriction upon the number of our Fellows is unwise, inasmuch as we narrow our influence and diminish our revenues thereby; and, by way of a still more unpleasant suggestion, it is hinted that, by such limitations, we lay ourselves open to the charge of a desire to arrogate to ourselves the position of the elect of science.

With respect to the first objection, I venture to point out that the influence of the Society upon the advancement of science is not by any means measured either by its numerical strength or by the amount of the funds at its disposal.

And, as to the second charge or insinuation, if it is worth while to meet it at all (which may be doubtful), I am disposed to think that, in another than the invidious sense of the words, it is highly desirable that the Fellows of the Royal Society should regard themselves, and be regarded by others, as the elect of science. An organisation which was the direct product of the new birth of science in the days of Gilbert, of Galileo, and of Harvey; which was one of the earliest of the associations founded for the sole purpose of promoting natural knowledge; and which has so faithfully performed its functions that it is inseparably associated with all the great strides which science has made for two centuries, has insensibly and without effort become a recognised representative of men of science in these islands: as such, on the one hand, it is consulted by the Government on scientific questions; and, on the other hand, it claims the right to be heard by the Government on all questions of scientific interest. I believe it to be impossible that the Society should discharge the functions which it has not sought, but which have thus devolved upon it, satisfactorily, unless it really does consist, in one sense, of the elect of science; that is to say, unless every care is taken to keep its scientific character at the level of its scientific reputation, and to ensure that it shall be not the mere figure-head of the scientific body, but a living association of representative men engaged in all branches of scientific activity.

Those among my hearers whose memories go back forty years will remember that, at that time, the Society was in great danger of losing its scientific character, though it would doubtless have taken it a long time, and a good deal of perversity, to get rid of its scientific reputation. It had become the fashion to append F.R.S. to a name, and the scientific members where in danger of being swamped by the invasion of *dilettanti*. The aim of our eminent colleague, Sir William Grove, and his friends, who fought the battle of 1847, and thereby, to my mind, earned the undying gratitude of all who have the interests of science at heart, was not to create an academy of immortals, but to save the Fellowship of the Society from becoming a sham and an imposture. And they succeeded in their object by carrying a measure of reform which embodied two principles—the first, that of the practical responsibility of the Council for the elections, the second, that of the limitation of the number of candidates annually elected. The result of the steady adherence of the Society to these principles for thirty-eight years is that, year by year, the Society has approached more and more closely to that representative character which, I cannot but think, it is eminently desirable it should possess.

During a great part of this time I have enjoyed more and closer opportunities than most people of watching the working of our system. Mistakes have been made now and then, no doubt, for even members of Council are fallible; but it is more than thirty years since the propriety of the selections made by the Council has been challenged at a general meeting; and I have never heard a question raised as to the conscientiousness with which the work is done, or as to the desire of the Council to mete out even-handed justice to the devotees of all branches of science. I am very strongly of opinion that if the Royal Society were a "Chamber of Science," subject to dissolution, and that after such dissolution a general election, by universal suffrage of the members of all scientific bodies in the kingdom, took place, an overwhelming majority of the present Fellows would be re-elected.

Such being my conviction, it is natural that I should express a fervent hope that the Society will never be tempted to depart from the principles of the method by which, at present, it recruits its strength. It is quite another question, however, whether it is desirable to retain the present limit to our annual addition or to increase it.

There is assuredly nothing sacred in the number 15; nor any good reason that I know of for restricting the total strength of our home list to 460 or 470; so long as our recruits approve themselves good soldiers of science the more we enrol the better. And if I may pursue the metaphor, I will add that I do not think it desirable that our corps should consist altogether of general officers. Any such exclusiveness would deprive us of much useful service, and seriously interfere with the representative character in which our strength lies. I think we ought to be in touch with the whole world of science in the country, and constitute a microcosm answering to that macrocosm. Those who are in favour of making a change observe that the limit of fifteen was fixed nearly forty years ago; that the number of those who occupy themselves seriously with science and attain a position which would undoubtedly have brought them into the Society at that time, has increased and is constantly increasing; and that it is undesirable that we should be compelled to leave out of our body, year after year, persons whom we should be very glad to see in it. On the other hand, it is to be recollected that a change once made can hardly be revoked, and that, in view of the importance of such a step, the Society will do well to make sure of the consequences before taking it.

I have thought it desirable to raise the question, not for the purpose of suggesting any immediate action—for my personal opinion is that, at present, no change is desirable—but in order that the attention of the Fellows may be directed to a matter which I think is sure to come before them in a practical shape before many anniversaries go by. And, whenever that time arrives, I think another problem may possibly offer itself for solution. Since this Society was founded, English-speaking communities have been planted and are increasing and multiplying in all quarters of the globe—to use a naturalist's phrase, their geographical distribution is "world wide." Wherever these communities have had time to develop, the instinct which led our forefathers to come together for the promotion of natural knowledge has worked in them and produced most notable results. The quantity and quality of the scientific work now being done in the United States moves us all to hearty admiration; the Dominion of Canada, and our colonies in South Africa, New Zealand, and Australia, show that they do not mean to be left behind in the race; and the scientific activity of our countrymen in India needs no comment.

Whatever may be the practicability of political federation for more or fewer of the rapidly growing English-speaking peoples of the globe, some sort of scientific federation should surely be possible. Nothing is baser than scientific Chauvinism, but still blood is thicker than water; and I have often ventured to dream that the Royal Society might associate itself in some special way with all English-speaking men of science; that it might recognise their work in other ways than by the rare opportunities at present offered by election to our foreign Fellowship, or by the award of those medals which are open to everybody; and without imposing upon them the responsibilities of the ordinary Fellowship, while they must needs be deprived of a large part of its privileges. How far this aspiration of mine may be reciprocated by our scientific brethren in the United States and in our colonies I do not know: I make it public, on my own responsibility, for your and their consideration.

I am anxious to call the attention of the Fellows to an alteration in our rules, in virtue of which it is hoped that the valuable library of the Society will be made more extensively useful to them by being accessible up to a later hour than heretofore, and by better provision for the comfort and convenience of those who desire to read or write in the Society's rooms.

The funds of the Society have been augmented in various ways during the past year.

The value of the fee for the Croonian Lecture has been increased from 2*l.* 18*s.* 9*d.* to about 50*l.* a-year, by the falling in of certain leases.

Allusion was made in the Treasurer's address last year to the Darwin Memorial. I am happy to say that Mr. Boehm's admirable statue was formally and publicly accepted by H.R.H. the Prince of Wales, on behalf of the Trustees of the British Museum, last summer, and now adorns the entrance hall of the Natural History Museum at South Kensington. The balance of the sum raised, amounting to 2000*l.*, has been handed over to the Royal Society, and the interest thereof will be employed under the name of the "Darwin Fund for the Promotion of Biological Research," in any way the President and Council may think fit. I sincerely trust that this fund may be increased from time to time, as the Donation Fund, founded by Dr. Wollaston, has been; and that its beneficent influence on the progress of biological science may thus keep green the memory of the great man whose name it bears, in the way which, assuredly, would have been most agreeable to himself.

I am sure that I may express your acknowledgments to Mr. James Budgett for the repetition of his liberal donation of 100*l.* in aid of the cost of publication of Prof. Parker's important and elaborate monographs on the vertebrate skull, one of which occupies a whole part of the *Transactions*, and is illustrated by thirty-nine quarto plates.

We are indebted to the subscribers to the Henry Smith Memorial for the marble replica of the bust by Mr. Boehm of that eminent mathematician and most accomplished scholar, which now ornaments our library. The Fine Art Society has presented Mr. Flameng's etching of the portrait of your President, painted by the Hon. John Collier.

Among the presents to the library, I may particularly mention the second volume of Prof. G. Retzius' valuable and splendidly illustrated work, "Das Gehör-organ der Wirbelthiere," and "Les Habitants de Surinam," by the Prince Roland Bonaparte, by their respective authors, and four volumes of the *Challenger* Report, by Her Majesty's Stationery Office.

Five numbers of the *Proceedings* (about 880 pages) have appeared since the last Anniversary. Only one part of the *Philosophical Transactions* has been as yet published; but two other parts (Parts I. and II. for 1885) are passing simultaneously through the press.

The possibility of devising means by which papers read before us may be published more rapidly, has seriously engaged the attention of the officers of the Society, and I trust that, before long, the Council may have some well-conceived plan for achieving that end brought under their consideration. While all will agree in deprecating unnecessary retardation, it must be remembered that a certain delay is absolutely necessary, if the Committee of Papers is to discharge with due care its important function of arriving at a sound judgment, after considering the opinions of responsible specialists on the merits of each paper submitted to it. In substance, I do not think that we can hope to better our present arrangements; all that can be asked is, that they should be improved in some details, and more especially that the time which necessarily intervenes between presentation and publication should be minimised.

The preparation of copy for the Catalogue of Scientific Papers, decade 1874—85, now approaches completion. A total of 290 series have been indexed, giving 85,000 title slips, written, checked, and distributed. This number, which is within 10,000 of that contained in the two volumes of the preceding decade, nearly exhausts the material in our own library; it remains to supplement this by reference to other libraries.

At the meeting on the 18th of June last, our Fellow, Prof. Roy, communicated to the Council the project entertained by himself, Dr. Graham Brown, of Edinburgh, and Mr. Sherington (G. H. Lewes Student, Cambridge), of proceeding to Spain with a view of investigating the nature of cholera, and requested the assistance of the Royal Society.

In view of the great practical importance of such an investigation, and the desirableness of making a new attempt to solve a problem about which highly competent inquirers have arrived at contradictory results, the President and Council resolved to do everything which lay in their power to assist Dr. Roy and his colleagues. The Secretary was instructed to inquire of the Spanish Minister whether the proposed investigations would be agreeable to the Spanish authorities, and whether Dr. Roy might expect to obtain facilities and assistance. On the receipt of a courteous and sympathetic letter from his Excellency, the Secretary was further instructed to inform the Foreign Office of Dr. Roy's expedition, and to request that Her Majesty's Government would afford him and his colleagues all the assistance in their power. Moreover, 150*l.* was granted from the Donation Fund in aid of the expenses of the undertaking, which were shared between the Royal Society and the Society for the Advancement of Medicine by Research.

I am sure the Fellows of the Society will join with me in congratulating Dr. Roy, Dr. Brown, and Mr. Sherington on having returned safe and sound from an adventure in which the interest of scientific inquiry must have been heightened by a considerable spice of personal danger. Dr. Roy has furnished me with a brief preliminary report of the work done, the substance of which I proceed to lay before the Society.

The members of the Commission met with very serious difficulties in their attempts to study the pathology of cholera in Spain, where they spent three months; but owing to the powerful support which was given them by the English Embassy in Madrid, they were able eventually to pursue their studies in a satisfactory manner. At Aranjuez and Madrid they obtained free access to the cholera hospitals, and made nearly thirty autopsies of typical cholera cases within very short periods after death. From all of these cases they were able to obtain material for cultivation and thus to make a large series of investigations on the different forms of micro-organisms which are found in the tissues and intestinal contents of cholera cases. Owing, however, to the impossibility of obtaining animals for inoculation, and reagents of various kinds, they were unable to complete their inquiry in Spain, and they were obliged to leave the investigations of certain points until their return to England. They have directed their attention chiefly to the relation which the comma bacillus, first described by Koch, bears to the cholera process, and they hope to be able to make important additions to our knowledge of this important subject. They are at present engaged in completing their work, and in the course of a few weeks they hope to be able to present their full report to the Royal Society.

The Marine Biological Association, to the funds of which the Royal Society made a substantial contribution last year, is making good progress. A site for building has been granted by the War Office, at Plymouth; plans have been prepared, and if the Treasury will follow the precedent which it has so largely and beneficially adopted in educational matters, of helping those who help themselves, as I am glad to say my lords seem inclined to do, I trust that, before long, the laboratory will be in working order.

The prosecution of the borings into the Delta of the Nile, which reference has been made on previous Anniversaries, have unfortunately been hindered by various obstacles. Quite recently I have been favoured by Col. H. Maitland, R.E., with an account of the borings made near Rosetta, in which a depth of 84 feet was reached without apparently attaining the bottom of the fluviatile deposits; and I hope that circumstances may shortly permit the resumption of the original project of carrying a line of borings across the Valley of the Nile on the parallel of Tantah or thereabouts.

In the meanwhile the Committee in charge of the investigation has presented a report by Prof. Judd on the results of the examination of the borings already made. I have been favoured by Prof. Judd with the following brief summary of these results, which have been fully fully set forth in a paper read at the first meeting of the Society after the recess.

Although two of the recent borings in the Nile Delta have attained depths of 73 and 84 feet respectively, yet neither of them has reached the rocky floor of the old Nile Valley, nor, indeed, have they afforded any indications of an approach to the solid rock. The samples of the Delta deposits obtained by these boring operations are found to be in all cases mixtures in varying proportions of Nile mud, or material carried in suspension by the river, and desert sand, or particles swept up from the surrounding districts by the action of winds. The study of these materials by the aid of the microscope has revealed a number of facts which may be made the basis of generalisations of considerable interest to geologists.

The minerals present in these sands and muds are found to be such as characterise the granitic and highly crystalline metamorphic rocks; there can be little doubt, therefore, that the vast regions included within the Nile basin are in the main composed of rocks belonging to those classes, or of sedimentary deposits derived from them.

Of still greater interest is the fact that the fragments of felspars and other complex silicates in the Delta deposits exhibit but slight evidences of kaolinisation or other chemical change. This points to the conclusion that, in rainless districts drained by the Nile, the disintegration of rocks is effected by mechanical rather than by chemical agencies. A very striking confirmation of this conclusion is afforded by the study of the composition of the waters of the Nile, our knowledge of which has been greatly advanced by the recent researches by Dr. C. M. Tidy. In spite of the circumstance that the waters of the Nile must undergo great concentration during its passage of 1400 miles through regions of exceptional heat and drought, it is found that those waters actually hold in solution little more than one-half the percentage of mineral matter which is present in the river waters of temperate and rainy regions. The chemical disintegration of rocks being so largely due to the action of rain and vegetation, it is not surprising to find that where these agencies are almost entirely absent the rocks exhibit but few signs of chemical change.

The Krakatão Committee, which is now rather a large one, consisting of thirteen members, has been steadily at work during the year; and the discussion of the very varied and large mass of data has been undertaken by sub-committees, dealing respectively with the following branches:—

Geological—including eruption and earthquake phenomena, and the geological features of the distribution of dust and pumice.

Meteorological (A)—including air-waves, sounds, and the geographical distribution of dust and pumice.

Meteorological (B)—including twilight effects, coronal appearances, cloud haze, coloured sun, moon, &c.

Magnetic and electric phenomena.

Tidal waves.

With the exception of the last-named Sub-Committee, viz. that upon Tidal Waves, of which the work has been delayed by the illness of Sir F. Evans, all the reports are now in a forward state, and there seems to be every prospect of the work being concluded in the course of a very few months.

The question of the proper administration of the funds administered on behalf of the Government by the representatives of the Royal Society and of other scientific bodies, who constitute the Government Grant Committee, has frequently been debated with much care by the President and Council, who are held responsible for the final assignment of the grant by the Government.

On the 20th of May last the Council determined, once again, to devote special attention to the subject, and on the 25th June the minutes will inform you that the following resolutions were passed:—

"That in every case of renewed application for a personal grant, after such grant has been received by the applicant in two consecutive years, the application be made not less than three months before it is to be considered, accompanied by a full statement of the case from the applicant, and that before being presented to the Committee, it be referred by the Council to two referees, who shall report to the Council on its merits."

"That the Secretaries be instructed to return to the applicants for aid from the Government Grant such applications as do not in all particulars comply with the conditions laid down in the circular to applicants."

It is very desirable that our intention to enforce the latter resolution strictly should be widely promulgated. I may add that we have considerable reason to complain that too frequently those who have obtained grants through the Committee make no report of the work done to the Society, but leave information on that head to reach us as it may through the publications in which the results obtained by the grantee are made known.

Nineteen large royal quarto volumes of the Official Reports on the Scientific Results of the *Challenger* Expedition have now been issued from the press. These contain thirty-seven zoological, three botanical, and eight physical and chemical reports, together with the narrative of the voyage, which contains the general scientific results of the Expedition. Six more volumes are now passing through the press, a considerable part of each being already printed off. The work connected with the remaining memoirs is in a forward state. The whole of the investigations and the manuscript will be completed during the next financial year, and in the course of the year 1887 the whole of the Reports will be published, and the work connected with the Expedition brought to a close.

In the Treasurer's address last year the Society was fully informed of the action taken by the President and Council in the matter of the position of this country with respect to the international "Bureau des Poids et Mesures." I am happy to be able to report to the Society that, last December, we received a letter from the Treasury, stating that my Lords had asked the Secretary of State to instruct the British Ambassador at Paris to make known to the Comité International des Poids et Mesures that Her Majesty's Government were willing to join the Convention on the terms described in our Secretary's letter of the 18th August, 1884, and that the proposal had been accepted.

Your President is, *ex officio*, Chairman of the Board of Visitors of the Royal Observatory. As such, it was my duty to preside at a recent meeting of that body, when my colleagues agreed to recommend the adoption of a day, commencing at midnight, in all observatories and in the *Nautical Almanac*, from and after the commencement of the year 1891.

Much to my regret, I have been unable to take part in the work of the City and Guilds Institute during the past year, but I have reason to know that considerable progress has been made towards the attainment of its object—the advancement of technical education in London and in the provinces. The Finsbury Technical College is fulfilling its purpose in the most satisfactory manner, and its day and evening classes are so numerously attended that an extension of the building is under consideration. About 250 technical classes in different parts of the Kingdom are now affiliated to the Institute, and some of them are already developing into efficient technical schools. The assistance which the Institute is enabled to afford to these classes is restricted by want of means; but there can be no doubt that far larger opportunities of obtaining evening instruction in the application of the different branches of science to industry are afforded to the artisans of London now than was the case even four or five years ago.

Large additions have been made to the equipment of the Central Institution at South Kensington. The engineering laboratory and the extensive chemical and physical laboratories are organised, and the systematic instruction of students has commenced. Scholarships of the value of 30*l*. a year, tenable for three years, have been offered to, and accepted by, the Governors of a number of public and other schools. These scholarships are to be awarded by the head-master (not necessarily on the result of a competitive examination) to any pupil who is competent to pass the entrance examination of the Central Institution.

The City and Guilds Institute is the outcome of the perception of the necessity for technical education, in the interests of industry, by the wealthiest city and the wealthiest guilds in the world; it may, therefore, seem singular that the chief obstacle to the proper development of the important schools which it has founded is poverty. Such, however, I understand to be the case. The Central Institution requires an assured income of at least 15,000*l.* a year if it is to work properly; but the joint resources of the City and Guilds of London, at present, appear to be able to afford it only a precarious, annually-voted, subsidy of 9000*l.* a year—far less, that is to say, than the private income of scores of individual Londoners. In Germany, a similar institution would demand and receive 20,000*l.* a year as a matter of course; but Englishmen are famous for that which a perplexed Chancellor of the Exchequer (I think it was) once called their "ignorant impatience of taxation," and there is no occasion on which they so readily display that form of impatience as when they are asked for money for education, especially scientific education. I am bound to add, however, that my experience on the Council and Committees of the Institute has left no doubt on my mind that my colleagues have every desire to carry out the work they have commenced thoroughly; and that the money difficulty will disappear along with certain other difficulties which, I am disposed to think, need never have arisen.

Such are the chief matters of business, if I may so call them, which it is proper for me, in my Presidential capacity, to bring before the Society. But it has been not unusual, of late years, for the occupant of the Chair to offer some observations of a wider bearing for the consideration of the Society; and I am the more tempted to trespass upon your patience for this purpose, as it is the last occasion on which I shall be able to use, or abuse, the President's privileges.

So far as my own observations, with respect to some parts of the field of natural knowledge, and common report, with respect to others, enable me to form an opinion, the past year exhibits no slackening in the accelerated speed with which the physical sciences have been growing, alike in extent and in depth, during several decades. We are now so accustomed to this "unhasting but unresting" march of physical investigation; it has become so much a part of the customary course of events, that, with every day, I might almost say with every hour, something should be added to our store of information respecting the constitution of nature, some new insight into the order of the cosmos should be gained, that you would probably listen with incredulity to any account of the year's work which could not be summed up in this commonplace of Presidential addresses.

Nor shall I be chargeable with innovation if I add that there is no reason to suspect that the future will bring with it any retardation in the advance of science. The adverse influences, which, in the middle ages, arrested the work commenced by the older Greek philosophers, are so much weakened that they no longer offer any serious obstacle to the growth of natural knowledge; while they are powerless to prevent the extension of scientific methods of inquiry and the application of scientific conceptions to all the problems with which the human mind is confronted. If any prophecy is safe of fulfilment, it is that, in the twentieth century, the influence of these methods and conceptions will be incomparably greater than it is now; and that the inter-penetration of science with the common affairs of life, which is so marked a feature of our time, will be immeasurably closer. For good or for evil, we have passed into a new epoch of human history—the age of science.

It may seem superfluous that I should adduce evidence in support of propositions which must have so much of the nature of truisms to you who are sharers in the work of science and daily witnesses of the effects of its productive energy. But the proverbial tendency of familiarity to be incompatible with due respect is noticeable even in our appreciation of the most important truths, and our strongest convictions need furbishing up now and then, if they are to retain their proper influence. I certainly cannot accuse myself of ever having consciously entertained a low estimate of the past work or the future progress of science; but, a few months ago, enforced leisure and the attainment of an age when retrospection tends to become a habit, not to say a foible, led me to look at the facts anew; and I must confess that the spectacle of the marvellous development of science, alike in theory and practice, within my own life-time, appeared to me to justify a faith, even more robust than mine, in its future greatness.

For, if I do not greatly err, the greater part of the vast body of knowledge which constitutes the modern sciences of physics, chemistry, biology, and geology, has been acquired, and the widest generalisations therefrom have been deduced, within the last sixty years; and, furthermore, the majority of those applications of scientific knowledge to practical ends, which have brought about the most striking differences between our present civilisation and that of antiquity, have been made within that period of time.

To begin with the latter point—the practical achievements of science. The first railway for locomotives, which was constructed between Stockton and Darlington, was opened in September, 1825, so that I have the doubtful advantage of about four months' seniority over the ancestral representative of the vast reticulated fetching and carrying organism which now extends its meshes over the civilised world. I confess it fills me with astonishment to think that the time when no man could travel faster than horses could transport him, when our means of locomotion were no better than those of Achilles or of Ramses Maimun, lies within my memory. The electric telegraph, as a thing for practical use, is far my junior. So are arms of precision, unless the old rifle be regarded as such. Again, the application to hygiene, and to the medical and surgical treatment of men and animals, of our knowledge of the phenomena of parasitism, and the very discovery of the true order of these phenomena, is a long way within the compass of my personal knowledge.

It is unnecessary for me to enumerate more than these four of the many rich gifts made by science to mankind during the last sixty years. Arresting the survey here, I would ask if there is any corresponding period in previous history which can take credit for so many momentous applications of scientific knowledge to the wants of mankind? Depreciators of the value of natural knowledge are wont to speak somewhat scornfully of these and such-like benefactions as mere additions to material welfare. I must own to the weakness of believing that material welfare is highly desirable in itself, and I have yet to meet with the man who prefers material illfare. But even if this should be, as some may say, painful evidence of the materialistic tendencies incidental to scientific pursuits, it is surely possible, without much ingenuity, or any prejudice in favour of one or other view of the mutual relations of material and spiritual phenomena, to show that each of these four applications of science has exerted a prodigious influence on the moral, social, and political relations of mankind, and that such influence can only increase as time goes on.

If the senseless antipathies, born of isolation, which formerly converted neighbours, whether they belonged to adjacent families or to adjacent nations, into natural enemies, are dying away, improved means of communication deserve the chief credit of the change; if war becomes less frequent, it will be chiefly because its horrors are being intensified beyond bearing by the close interdependence and community of interest thus established between nations, no less than by the improvement of the means of destruction by scientific invention. Arms of precision have taken the mastery of the world out of the hands of brute force and given it into those of industry and intelligence. If railways and electric telegraphs have rendered it unnecessary that modern empires should fall to pieces by their own weight as ancient empires did, arms of precision have provided against the possibility of their being swept away by barbarous invasions. Health means not merely wealth, not merely bodily welfare, but intellectual and moral soundness; and I doubt if, since the time of the father of medicine, any discovery has contributed so much to the promotion of health and the cure of disease as that of the part played by fungoid parasites in the animal economy, and that of the means of checking them, even though, as yet, unfortunately it be only in a few cases.

But though these practical results of scientific work, during only two generations, are calculated to impress the imagination, the Fellows of this Society know well enough that they are of vastly less real importance than the additions which have been made to fact and theory and serviceable hypothesis in the region of pure science. But it is exactly in these respects that the record of the past half century is so exceptionally brilliant. It is sometimes said that our time is a day of small things—in science it has been a day of the greatest things, for, within this time, falls the establishment, on a safe basis, of the greatest of all the generalisations of science, the doctrines of the Conservation of Energy and of Evolution.

As for work of less wide scope, I speak in the hearing of those who can correct me if I am wrong, when I say that the larger moiety of our present knowledge of light, heat, electricity, and magnetism, has been acquired within the time to which I refer; and that our present chemistry has been in great part created, while the whole science has been remodelled from foundation to roof. It may be natural that progress should appear most striking to me among those sciences to which my own attention has been directed, but I do not think this will wholly account for the apparent advance "by leaps and bounds" of the biological sciences within my recollection. The cell theory was the latest novelty when I began to work with the microscope, and I have watched the building of the whole vast fabric of histology; I can say almost as much of embryology, since Von Baer's great work was published in 1828. Our knowledge of the morphology of the lower animals and plants, and a great deal of that of the higher forms, has very largely been obtained in my time; while physiology has been put upon a totally new foundation, and, as it were reconstructed, by the thorough application of the experimental method to the study of the phenomena of life, and by the accurate determination of the purely physical and chemical components of these phenomena. The exact nature of the processes of sexual and non-sexual reproduction has been brought to light. Our knowledge of geographical and geological distribution, and of the extinct forms of life, has been increased a hundredfold. As for the progress of geological science, what more need be said than that the first volume of Lyell's "Principles" bears the date of 1830?

This brief enumeration of the salient achievements of science in the course of the last sixty years is sufficient not only to justify what I have said respecting their absolute value, but to show how much it excels, both in quantity and quality, the work produced in any corresponding period since the revival of science. It suggests, as I have said, that science is advancing and will continue to advance with accelerated velocity.

It seems to me, in fact, not only that this is so, but that there are obvious reasons why it must be so. In the first place, the interdependence of all the phenomena of nature is such that a seemingly unimportant discovery in one field of investigation may react in the most wonderful manner upon those which are most widely remote from it. The investments of science bear compound interest. Who could have imagined that a curious inquiry into the relations of electricity with magnetism would lead to the construction of the most delicate instruments for investigating the phenomena of heat; to means of measuring not only the smallest intervals of time, but the greatest depths of the ocean; to methods of exploring some of the most hidden secrets of life? What an enormous revolution would be made in biology, if physics or chemistry could supply the physiologist with a means of making out the molecular structure of living tissues comparable to that which the spectroscope affords to the inquirer into the nature of the heavenly bodies. At the present moment the constituents of our own bodies are more remote from our ken than those of Sirius, in this respect. In the next place, the vast practical importance of the applications of scientific knowledge has created a growing demand for technical education based upon science. If this is to be effective, it means the extension of scientific teaching to all classes of the community, and the encouragement and assistance of those who are fit for the work of scientific investigation to adopt that calling. Lastly, the attraction of the purely intellectual aspects of science and the rapid growth of a sense of the necessity of some knowledge of the phenomena of nature, and some discipline in scientific methods of inquiry, to every one who aspires to take part in, or even to understand, the tendencies of modern thought, have conferred a new status upon science in the seats of learning, no less than in public estimation.

Once more reverting to reminiscence, the present state of scientific education surely presents a marvellous and a most satisfactory contrast to the time, well within my memory, when no systematic practical instruction in any branch of experimental or observational science, except anatomy, was to be had in this country; and when there was no such thing as a physical, chemical, biological, or geological laboratory open to the students of any University, or to the pupils of any school, in the three kingdoms. Nor was there any University which recognised science as a faculty, nor a school, public or private, in which scientific instruction was represented by much more than the occasional visit of a vagrant orrery.

At the present moment, any one who desires to obtain a thoroughly scientific training has a choice among a dozen institutions; and elementary scientific instruction is, so to speak, brought to the doors of the poorer classes. If the rich are debarred from like advantages, it is their own affair; but even the most careful public school education does not now wholly exclude the knowledge that there is such a thing as science from the mind of a young English gentleman. If science is not allowed a fair share of the children's bread, it is at any rate permitted to pick up the crumbs which fall from the time-table, and that is a great deal more than I once hoped to see in my life-time.

I have followed precedent in leading you to the point at which it might be fair, as it certainly would be customary, to end by congratulating you, as Fellows of the Royal Society, on the past progress and the future prospects of the work which, for two centuries, it has been the aim of the Society to forward. But it will perhaps be more profitable to consider that which remains to be done for the advancement of science, than to "rest and be thankful" in the contemplation of that which has been done.

In all human affairs the irony of fate plays a part, and in the midst of our greatest satisfactions, "surgit amari aliquid." I should have been disposed to account for the particular drop of bitterness to which I am about to refer, by the sexagenarian state of mind, where it not that I find the same complaint in the mouths of the young and vigorous. Of late years it has struck me, with constantly increasing force, that those who have toiled for the advancement of science are in a fair way of being overwhelmed by the realisation of their wishes. We are in the case of Tarpeia, who opened the gates of the Roman citadel to the Sabines, and was crushed under the weight of the reward bestowed upon her. It has become impossible for any man to keep pace with the progress of the whole of any important branch of science. If he were to attempt to do so, his mental faculties would be crushed by the multitudes of journals and of voluminous monographs which a too fertile press casts upon him. This was not the case in my young days. A diligent reader might then keep fairly informed of all that was going on, without robbing himself of leisure for original work, and without demoralising his faculties by the accumulation of unassimilated information. It looks as if the scientific, like other revolutions, meant to devour its own children; as if the growth of science tended to overwhelm its votaries; as if the man of science of the future were condemned to diminish into a narrower and narrower specialist, as time goes on.

I am happy to say that I do not think any such catastrophe a necessary consequence of the growth of science; but I do think it is a tendency to be feared, and an evil to be most carefully provided against. The man who works away at one corner of nature, shutting his eyes to all the rest, diminishes his chances of seeing what is to be seen in that corner; for, as I need hardly remind my present hearers, that which the investigator perceives depends much more on that which lies behind his sense-organs than on the object in front of them.

It appears to me that the only defence against this tendency to the degeneration of scientific workers, lies in the organisation and extension of scientific education, in such a manner as to secure breadth of culture without superficiality; and, on the other hand, depth and precision of knowledge without narrowness.

I think it is quite possible to meet these requirements. There is no reason, in the nature of things, why the student who is destined for a scientific career should not, in the first place, go through a course of instruction such as would insure him a real, that is to say, a practical acquaintance with the elements of each of the great divisions of mathematical and physical science; nor why this instruction in what (if I may borrow a phrase from medicine) I may call the institutes of science, should not be followed up by more special instruction, covering the whole field of that particular division in which the student eventually proposes to become a specialist. I say not only that there is no reason why this should not be done, but, on the ground of practical experience, I venture to add that there is no difficulty in doing it. Some thirty years ago, my colleagues and I framed a scheme of instruction on the lines just indicated, for the students of the institution which has grown into what is now known as the Normal School of Science and Royal School of Mines. We have found no obstacles in the way of carrying the scheme into practice except such as arise, partly, from the limitations of time forced upon us from without; and, partly, from the extremely defective character of ordinary education. With respect to the first difficulty, we ought, in my judgment, to bestow at least four, or better five, years on the work which has, at present, to be got through in three. And, as regards the second difficulty, we are hampered not only by the ignorance of even the rudiments of physical science, on the part of the students who come to us from ordinary schools, and by their very poor mathematical acquirements, but by the miserable character of the so-called literary training which they have undergone.

Nothing would help the man of science of the future to rise to the level of his great enterprise more effectually than certain modifications, on the one hand, of primary and secondary school education, and, on the other, of the conditions which are attached by the Universities to the attainment of their degrees and their rewards. As I ventured to remark some years ago, we want a most favoured nation clause inserted in our treaty with educators. We have a right to claim that science shall be put upon the same footing as any other great subject of instruction, that it shall have an equal share in the schools, an equal share in the recognised qualification for degrees, and in University honours and rewards. It must be recognised that science, as intellectual discipline, is at least as valuable, and, as knowledge, is at least as important, as literature, and that the scientific student must no longer be handicapped by a linguistic (I will not call it literary) burden, the equivalent of which is not imposed upon his classical compeer.

Let me repeat that I say this, not as a depreciator of literature, but in the interests of literature. The reason why our young people are so often scandalously and lamentably deficient in literary knowledge, and still more in the feeling and the desire for literary excellence, lies in the fact that they have been withheld from a true literary training by the pretence of it, which too often passes under the name of classical instruction. Nothing is of more importance to the man of science than that he should appreciate the value of style, and the literary work of the school would be of infinite value to him if it taught him this one thing. But I do not believe that this is to be done by what is called forming one's self on classical models, or that the advice to give one's days and nights to the study of any great writer, is of much value. "Le style est l'homme même," as a man of science who was a master of style has profoundly said; and aping somebody else does not help one to express one's self. A good style is the vivid expression of clear thinking, and it can be attained only by those who will take infinite pains, in the first place, to purge their own minds of ignorance and half knowledge, and, in the second, to clothe their thoughts in the words which will most fitly convey them to the minds of others. I can conceive no greater help to our scientific students than that they should bring to their work the habit of mind which is implied in the power to write their own language in a good style. But this is exactly what our present so-called literary education so often fails to confer, even on those who have enjoyed its fullest advantages; while the ordinary schoolboy has rarely been even made aware that its attainment is a thing to be desired.

I venture to lay these last observations before you, because we have heard a good deal lately of schemes for the remodelling of the University of London, which has done so much, through its Faculties of Science and Medicine, to promote scientific instruction. As a member of the Senate of the University I am necessarily greatly interested in such projects, and I greatly regret that I have been unable to take part in the recent action concerning them. This is not the time or the place for the discussion of any of these proposals, but many of my hearers must be as warmly interested in them as I am myself, and it may not be out of place to submit two questions for their serious consideration.

In the interests of science, will any change be satisfactory which does not lighten the linguistic burden at present imposed on students of science and of medicine by the matriculation examination?

And again, in the interests of science, will any change be satisfactory which does not convert the examining University into a teaching University? And, by that last term, I do not mean a mere co-operative society of teacher-examiners, but a corporation which shall embrace a professoriate charged with the exposition and the advancement of the higher forms of knowledge in all its branches.

The future both of pure science and of medicine in this country is, I think, greatly interested in the answer which Fellows of this Society, after due meditation, may be disposed to give to these questions.

I have to announce an unusually large number of changes in the staff of the Society.

Last December we regretted to receive the resignation of Mr. Walter White, so long our Assistant Secretary, whose faithful and efficient services, continued for more than forty years, are well known to all the Fellows of the Society. The minutes of the Council record our appreciation of Mr. White's services, and our endeavour to give as substantial a form as possible to our hearty recognition of his deserts. The vacancy thus caused has been filled up by the appointment of Mr. Herbert Rix, whose work since he has held the office of clerk has been such as to justify the confidence of the officers, not only that the functions hitherto discharged by the Assistant Secretary will be as well performed as heretofore; but that, if the interest of the Society should demand it, we may throw still more important duties upon him. I receive the most favourable reports of the efficiency of Mr. James, who has been appointed to the office of clerk in place of Mr. Rix.

Notwithstanding my release from all serious work, my health remained so very indifferent for some months after my return to England that I felt it my duty to the Society to bring the question of my resignation of the Presidency, on the present Anniversary, before the Council which met on May 20. My colleagues were kind enough to wish that my final decision should be deferred, and I need hardly say how willing I should have been to retain my honourable office if I could have done so with due regard to the interests of the Society, and, perhaps I may add, of self-preservation.

I am happy to say that I have good reason to believe that, with prolonged rest—by which I do not mean idleness, but release from distraction and complete freedom from those lethal agencies which are commonly known as the pleasures of society—I may yet regain so much strength as is compatible with advancing years. But, in order to do so, I must, for a long time yet, be content to lead a more or less anchoritic life. Now it is not fitting that your President should be a hermit, and it becomes me, who have received so much kindness and consideration from the Society, to be particularly careful that no sense of personal gratification should delude me into holding the office of its representative one moment after reason and conscience have pointed out my incapacity to discharge the serious duties which devolve upon the President, with some approach to efficiency.

I beg leave, therefore, with much gratitude for the crowning honour of my life which you have conferred upon me, to be permitted to vacate the chair of the Society as soon as the business of this meeting is at an end.

As I am of opinion that it is very undesirable that the President should even seem to wish to exert any influence, direct or indirect, on the action of the Fellows assembled in General Meeting, I am silent respecting the proposals embodied in the new list of the officers of the Society which my colleagues and I have unanimously agreed to submit for your consideration.

The President then proceeded to the presentation of the Medals:—

The Copley Medal is awarded to Prof. August Kekulé of Bonn, whose researches in organic chemistry, extended over the last five-and-thirty years, have been fruitful of results of high importance in chemical science. The great work of Prof. Kekulé's life, that which has raised him to the highest rank among the investigators of the day, is his general theory of the constitution of carbon compounds, in which the now universally accepted conception of the constitution of those compounds was first clearly and definitely stated.

A development of the fundamental theory led Kekulé to the discovery of the constitution of an exceedingly numerous and very complex class of compounds, which he has named the aromatic compounds, and his theory of the constitution of the aromatic compounds has suggested and guided innumerable investigations. The marvellous success obtained by many of his followers and pupils in building up artificially complex substances which had defied the efforts of all previous investigators, affords tangible evidence that Kekulé's labours have given us a deeper insight into the order of nature.

One of the Royal Medals is awarded to Prof. Hughes, F.R.S., for a series of experimental investigations in electricity and magnetism, which are remarkable alike for ingenuity of contrivance, for the simplicity of the apparatus employed, for the delicacy of the indications afforded, and for the wide applicability of the instruments invented to researches other than those for which they were originally designed.

The microphone, the induction balance, and the sonometer, are instruments by which inconceivably minute electrical and magnetic disturbances not only make themselves loudly audible, but may be definitely measured; and their application has opened up new lines of inquiry.

The other Royal Medal is awarded to Prof. E. Ray Lankester, F.R.S., for his labours, now extending over more than twenty years, in the field of animal morphology (especially invertebrate anatomy and embryology) and of palæontology.

Prof. Lankester has been active in many directions, and has everywhere left his mark, not only as an energetic teacher and accurate worker and a philosophical thinker; but as one who, in times when the example is more than ever valuable, has always been careful to remember that speculation should be the servant and not the master of the biologist.

The Davy Medal is awarded to Prof. Stas of Brussels.

Prof. Stas's great research, for which it is proposed that the Davy Medal be awarded to him, is that on atomic weights. There are probably no researches in chemistry, the results of which appeal so little to the imagination, and which are so little applauded, as those on atomic weights, yet for difficulty and importance they are hardly surpassed by any. The determination of these fundamental constants of chemistry has engaged the attention of many of the leading chemists, and before the time of M. Stas's experiments, an immense amount of careful labour had been bestowed on finding methods for the more accurate and complete purification of the compounds employed for the purpose.

The indefatigable and conscientious care which M. Stas has devoted to the re-determination of a certain number of the most important atomic weights, and the marvellous skill with which he has overcome the various difficulties which successively presented themselves, render his memoir on the subject one of the most remarkable and valuable of chemical monographs.

I regret to say that the state of M. Stas's health has not permitted him to be with us to-day, but the representative of his Sovereign, the King of the Belgians, in this country, has kindly consented to receive the medal for him.

M. le Baron Solvyns, I request your Excellency to be so good as to receive the medal awarded to M. Stas; and to assure him of the pleasure which it gives the Royal Society to show their sense of his high merits, by asking his acceptance of this memorial of his illustrious predecessor, Humphry Davy.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—In the Examination for Chemistry and Physics for 1st M.B. last June, an unusually large proportion of candidates were rejected. At the request of the Special Board for Medicine, the Examiners, Messrs. Pattison Muir, A. Scott, A. Schuster, and W. N. Shaw, have stated their opinion that the candidates showed very little mental training; they had almost no power of expressing clearly what they knew, whether facts, or conclusions from facts. Prof. Michael Foster has written a letter to Prof. Paget on this subject, partly derived from his recent experience in examining in Physiology in the 2nd M.B., and deploring the condition in which men enter the University, not only ignorant of Chemistry and Physics, but unprepared by any adequate discipline to receive the truths of experimental science. He believes no proper reform can come until the University makes such a change in the Previous or Preliminary Examination as shall permit a lad at school to study Chemistry and Physics, and give him time to do so by relieving him of some other subjects. The last clause is most important, and we are glad Prof. Foster emphasised it. The University requirements in the Preliminary Examinations determine the whole current of school work, and to move them in the direction of requiring, or at any rate permitting, Chemistry and Physics to be adequately taught at schools, should be a foremost object of scientific educationists.

Mr. R. G. Moulton, one of the most experienced lecturers on the University extension scheme, writes to advocate the establishing of a general organisation on a permanent basis. He points out that the best lecturers are lost when most valuable, owing to the lack of an assured position; also that the local committees need to be brought into connection with each other. A body also is needed which could seek and receive endowments. During the last ten years 50,000*l.* has been spent in the scheme, and 60,000 students have attended full courses of lectures.

The following Colleges offer Natural Science Scholarships or Exhibitions for open competition during the present and next month; the respective dates of examination being affixed:—Gonville and Caius, December 8; King's College, December 10; Jesus College, January 4; Christ's, Emmanuel, and Sidney-Sussex Colleges in common, January 5; St. John's College, December 10; Trinity College, December 10.

SCIENTIFIC SERIALS

Rivista Scientifico-Industriale, October 15.—On lateral atmospheric refraction, by Dr. G. Andries.—Transport and distribution of electricity by means of induced transformers: system of Zipernowsky, Deri, and Blathy, by Emilio Piazzolo.—On electric contrivances for illuminating fluids in scientific laboratories (four illustrations), by the editor.—On the microscopic organisms present in drinking-water: their life in waters charged with carbonic acid, by Dr. T. Leone.

THE *Journal of the Royal Microscopical Society*, vol. v. ser. ii part 5, October, contains:—On new British micro-fungi, by G. Massee (plate 13).—On erosion of the surface of glass when exposed to the joint action of carbonate of lime and colloids, by Dr. W. M. Ord.—On a septic microbe from a high altitude, by G. F. Dowdeswell.—On the use of the avicularian mandible in the determination of the chilostomatous Polyzoa, by Arthur W. Waters (plate 14).—The usual summary of current researches.

THE *American Naturalist* for October contains:—Mythic dry-paintings of the Novayos (illustrated), by W. Matthews.—The relations of mind and matter, by C. Morris.—A biography of the halibut, by G. B. Goode.—Traces of prehistoric man of the Watash, by John T. Campbell.—Editor's Table, Recent Literature, and General Notes.

THE *Victoria Royal Society Transactions*, vol. xxi. issued June 30, among other papers contains the following:—Evidences of a Glacial epoch in Victoria during post-Miocene times, by G. S. Griffiths.—The Phanerogama of the Mitta-Mitta Source Basin, II., by James Stirling.—Shingle on the east coasts of New Zealand, by W. W. Culcheth, M.Inst.C.E.—New or little-known Polyzoa, Part VII. (Plates 1 to 3), Part VIII. (Plates 1 to 5, by P. H. MacGillivray, M.A.—On the reproduction of the Ornithorhynchus, by P. H. MacGillivray, M.A.—On the Diabase rocks of the Buchan district; supplementary notes by A. W. Howett.—The meteorology of the Australian Alps, by James Stirling.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, November 19.—Prof. Moseley, F.R.S., in the chair.—Mr. A. D. Michael exhibited and described the remarkable nymphal stage of *Tegeocranus cepheiformis*, a species of the Oribatidæ, which he lately discovered for the first time in England. He has furthermore succeeded in tracing the whole life-history of this animal. The creature in its nymphal stage is exceedingly strange and beautiful. It carries on its back as concentric shields the dorsal portions of all its cast-skins, and these are bordered by projections each bearing a rose-leaf-like cuticular process of transparent membrane with chitinous nervures. The drawing of the nymph was first sent to Mr. Michael, two years ago, by Herr Pappe, of Bremen.—Mr. C. Stewart demonstrated, under the microscope, the stridulating apparatus of a species of *Sphærotherium*, differing in some respects from that described by Mr. Bourne (*infra*).—Dr. J. Murie exhibited and made remarks on the caudal end of the spine of a haddock with an arched deformity, recalling what is recorded of the so-called hump-backed cod (*Morrhua macrocephala*).—Mr. G. J. Fookes called attention to some twin-apples, of teratological interest. These were grown at Shepherd's Bush, upon a tree eighty years old, which last year was nearly barren, but this year produced abundantly, many of the fruits being good examples of syncarpy.—Prof. P. M. Duncan read a paper on the perignathic girdle of the Echinoidea. The author maintained that as the structures which give attachment to the muscles that protrude and retract the jaws of the Echinoidea (which are parts of the test surrounding the peristome within) are not homologous in all the families of the group, therefore it is unadvisable to retain the old name of "auricles." He suggests to substitute the term "perignathic girdle." The girdle consists of processes usually united above (though occasionally disconnected), and of "ridges" which connect the processes on the side remote from the ambulacra. The ridges are modifications of the inter-radial plates, the processes developments from the ambulacral plates. In the Cidaridæ, the muscular attachments are all on disconnected ridges, and there are no processes. In the Temnopleuridæ, Echinidæ, Echinometridæ, and Diadematidæ, the retractor muscles are attached to "processes" which are growths of the poriferous portions of the ambulacral plates; and the protractor muscles and ligament of the radiales are attached to the ridge which is developed on the inter-radial plates, and is united by suture to the base of the "process." In the Clypeastridæ there are disconnected growths which carry the jaws and have slight muscular attachments. In *Clypeaster* there are ten processes, each arising from an ambulacral plate; and there are no inter-radial structures like ridges. In *Laganum* there are five growths, each arising from a first inter-radial plate; hence these are the homologues of ridges. The Clypeastridæ may thus be divided into two groups, on account of the presence of processes in one, and of the homologues of ridges in the other.—Prof. Moseley communicated a paper on the anatomy of *Sphærotherium* by Mr. G. C. Bourne. The author mentioned that while the general exterior features and specific distinctions of the genus had been amply discussed, the internal structures had hitherto received scant attention. Among other anatomical peculiarities he describes a well-defined stridulating organ in the male. This consists of a prominent bolster-shaped swelling on the postero-external edge of the second joint of the second pair of copulatory appendages. The swelling occupies the entire margin of the joint, and shows a number of chitinous cross ridges and furrows. On the opposite interior surface of the last tergite are chitinous points. The former rasp-like organ of the second accessory appendages when rubbed rapidly against the latter produce a shrill note resembling that emitted by the house cricket. A true auditory organ exists in the antennary fossa beneath the eye. The tracheal system is unlike the majority of that of the Diplopoda, rather resembling that of Chilopoda and Insecta, though differing in the branched spiral filament not taking origin directly from the stigmata themselves. It appears that the tracheæ of *Sphærotherium* are a transition from those of the Julus type to those of the Scolopendra type. It would thus seem that the character of the tracheæ, the curved alimentary tract, the numerous chitinous pieces composing each segment, and the presence of a special hearing organ on the head, mark off the family Glomeridæ (to which *Sphærotherium* belongs) very sharply from the other families of the Diplopoda.—Prof. Moseley afterwards read extracts of letters from Mr. G. C. Bourne, who is now in the Chagos Archipelago, and from Mr. Sydney Hickson in the Celebes (Oxford graduates), and now investigating the natural history of the regions in question.—There followed a paper, contributions to South African botany, Orchideæ, part 2, by Mr. H. Bolus, with additional notes by Mr. N. E. Brown.

PARIS

Academy of Sciences, November 23.—M. Jurien de la Gravière, President, in the chair.—Observations of the minor planets made with the great meridian of the Paris Observatory during the third quarter of the year 1885, communicated by M. Mouchez.—Researches on the functions of Wrisberg's nerve, by M. Vulpian.—On a new theory of algebraic forms, by M. Sylvester.—On the sulphate of sparteine as a dynamic medicine and cure for the irregular action of the heart, by M. Germain Sée. This alkaloid (C_{15} or $C_{13}, H_{26}N_2$), obtained in 1850 by Stenhouse from *Spartium scoparium*, is found to be a sovereign remedy for feeble, irregular, and abnormal pulsation. It also instantaneously restores enfeebled circulation, while preserving or increasing muscular vigour.—Action of lime (milk of lime) on the vine attacked by mildew, by the Duchess de Fitz-James. The author regards this preparation as the most practical, efficacious, and economical for vines attacked by mildew in the south of France.—Note on Lagrange's interpolating formula as presented by M. Hermite in *Crelle's Journal*, vol. lxxxiv., by M. Bendixson.—Note on Kœnig's theorem regarding the living force animating a material system at a given moment, by M. Ph. Gilbert.—Application of the cryoscopic method to the determination of molecular weights, by M. F. M. Raoult. It is shown that by this method the molecular weight of any substance may be determined with great certainty, provided such substance, or one of its compounds, or one of its derivatives obtained by substitution, be soluble either in water, acetic acid, or benzene. It presents the further advantage that the results thus obtained are susceptible of verification in several ways.—Researches on hypophosphoric acid ($PHO_4,2HO$ or $PH_2O_8,4HO$), by M. A. Joly.—Heat of combustion of some substances of the fat series, by M. Louguinine. The substances here studied with a view to determining their heat of combustion are: paraldehyde; normal propionic acid and anhydride; normal propionic acid purified and analysed by the author; aldol.—Note on a new method of chloridation, by MM. Albert Colson and Henri Gautier. Two points are established: (1) that the perchloride of phosphorus allows the introduction of a determined quantity of chlorine into the homologues of benzene; (2) that the chlorine liberated by the perchloride of phosphorus acts on the benzenic hydrogen only after being substituted for the hydrogen of the lateral series. —On the presence of methylic alcohol in the products derived from the distillation of plants with water, by M. Maquenne.—On the gutta-percha of *Bassia* (Butyrospermum) *parkii*, G. Don, and its chemical composition, by MM. Ed. Heckel and Fr. Schlagdenhauffen. The gutta-percha obtained from this plant is shown to be in every respect comparable to, and in structure almost identical with, that yielded by the better-known *Isonandra gutta*, Hooker.—On the pretended circulation in the ganglionar cells of animal organisms, by M. W. Vignal.—Remarks on the acicular apparatus of some Echinidæ of the Chalk and Tertiary epochs, by M. Munier-Chalmas.—Note on a meteor observed in Paris on November 18, by M. Stanislas Meunier.—On the shower of meteors which may, perhaps, accompany the transit of the earth through the descending nucleus of Biela's comet on November 27, by M. Zenker.—A second reply to M. Charpentier respecting the functions of the several elements of the retina producing the sensations of light, colour, and form, by M. H. Parinaud.—Observations on MM. Martel and de Launay's note on certain fragments of human crania and a fragment of pottery found in the cave of Nabriguas, and said to be contemporary with *Ursus spelæus*, by M. Emile Cartailhac. The author, who has several times visited this cave, is satisfied that it has been exposed to frequent inundations, and that, consequently, the ground has been disturbed even since the beginning of the Quaternary period. Hence, although man was certainly contemporary with *Ursus spelæus* in the west of Europe, he did not live in association with that animal, but probably took possession of the Nabriguas and other similar caves after its extinction in Neolithic times. The potsherd in question has been subjected to the action of fire, and is evidently of comparatively recent date, washed into the cave by the flood waters.

THE "ENCYCLOPÆDIA BRITANNICA"

Encyclopædia Britannica. Ninth Edition. Vols. XVIII. and XIX. (Edinburgh: A. and C. Black, 1885.)

THESE two volumes are almost entirely occupied with letter P, and yet it is not finished. Though there are no articles of the tremendous length of some in the earlier volumes, still there are many of more than the average length and importance. In Vol. XVIII. we have such articles as Ornithology, by Prof. Newton; Parallax, by Mr. David Gill; Pacific Ocean, by Mr. John Murray; and Phosphorescence, by Prof. Pritchard. In Vol. XIX. again we have a valuable fragment on the Physical Sciences, by the late Clerk Maxwell; Pisciculture, by Mr. Browne Goode; Planarians, by Prof. L. V. Graaf; Polar Regions, by Mr. C. R. Markham; Physiology, by Prof. M. Foster, Prof. McKendrick, and Mr. S. H. Vines; and Pianoforte, by Mr. A. J. Hipkins. We have only space to notice at length the articles on Ornithology, Physiology, and Pianoforte.

Prof. Alfred Newton's article "Ornithology" stamps him as the first ornithological critic of the day, and his treatment of this most difficult subject is, as far as it goes, a model of scientific arrangement and elegant diction. He traces the history of ornithology from the very earliest times by a record of successive authors and their work, and then discusses the families of birds with a dissertation on the merits of the various systems which have been lately proposed, but it is in the record of recent ornithological work that we find the most conspicuous failure of Prof. Newton to do justice to his contemporaries. Whether want of space compelled the author to abridge this part of the subject we know not, but if the article "Ornithology" is supposed to be a history of the science down to the year 1884, the student of the future will greatly wonder at the omissions, not knowing how to attribute them to a critic whose account of the early history of the subject is so wonderfully complete and minute. It was doubtless a mere oversight on the part of the author to have attributed the completion of Gould's "Supplement to the Humming-birds" to Mr. Salvin instead of to Mr. Sharpe, but we should have expected to find some little account of the publications of the last-named ornithologist, whose name is not mentioned in connection with the "Catalogue of Birds in the British Museum," with which it is likely to be remembered in the history of ornithology, more than with the foundation of Dresser's "Birds of Europe," and with the second edition of Layard's "Birds of South Africa," with which Prof. Newton associates it. In the latter case Mr. Sharpe must be held to have done his work badly, as, despite his incorporation of all the excellent work of Mr. J. H. Gurney in his edition of "Layard," the latter ornithologist has a "knowledge of South African ornithology perhaps greater than that of any one else." No classification of birds as yet proposed satisfies Prof. Newton, any more than it does any other ornithologist; but Mr. Sharpe's publication of Sundevall's scheme of classification will *not* be considered "so much waste of time" by those who recognise that, with all its faults, it contains, like all well-matured schemes, many points of excellence and hints on classification in advance of his predecessors. The same must be said of Dr. Sclater's recent scheme, and also of Prof. Newton's own critical remarks in the present article. All are contributions towards a final natural arrangement of the class "*Aves*," if such indeed will ever be compassed. The arrangement of the British Museum "Catalogue" is well known to be faulty, but it is only by the complete description of every genus and its component species that a correct idea of their relations can ultimately be entertained, and to entirely ignore the new volumes of the "Catalogue" is at least matter for wonderment, seeing that already 4116 species have been described in its pages with their full synonymy up to date, while 196 species have been figured. Similarly Prof. Newton, in his enumeration of recent works on British ornithology, omits to mention Mr. Seebohm's name altogether, though the "History of British Birds" was far advanced towards completion in 1884. We might also complain of the scant justice done to Mr. Harting, whose popular work on the "Birds of Middlesex" was the forerunner, if not the exact model, of many of those books on county ornithology, space to mention which is found by Prof. Newton. No doubt some future historian will carry on the record of ornithological prowess from the point where it is left by Prof. Newton, but one thing is certain, that every subsequent writer will be indebted to the author for his facts concerning the early history of ornithology, which we believe to be one of the most complete and exhaustive records ever published.

The article "Physiology" in the last-issued volume is a threefold one of considerable length. Dr. Vines gives us an extended treatise on vegetable physiology, whilst Prof. McKendrick discusses in detail certain aspects of the physiology of the nervous system. Without detracting from the merit of these two pieces of work, which are full of valuable information, we may say at once that the section of the article written by Prof. Michael Foster, which precedes these, is that which will command most attention and indeed should be read by every student of science as well as by the intelligent layman who wishes to know the past, present, and future of the branch of science which is, perhaps more than any other, destined to influence the welfare of humanity. Prof. Foster's essay is in fact a very remarkable one; admirable in style, vigorous and lucid, it gives the reader the impression, which is well founded, that he is being shown the inner history of the growth and development of a great science by one who has the clear vision and unerring judgment of a master of his subject. Hereafter Prof. Foster's article will retain permanent value as the best exposition of the way in which the problems of physiology were regarded, both retrospectively and with a view to future progress, in the latter quarter of the nineteenth century.

Prof. Foster commences by defining physiology as "the study of the actions of living beings on their surroundings and correlatively of the action of the surroundings on the living being," whilst he points out that at an earlier period physiology comprised morphology and corresponded to what is now called biology.

Then follows a sketch of these "actions of a living being." They are brought under three heads:—(1)

Movements; dependent upon the contractions of muscles and the existence of mechanical contrivances connected therewith. (2) *Activity of the Nervous System;* in controlling in various ways and in relation to various external and internal conditions the before named movements. (3) *Chemical Changes;* these are briefly sketched as not only those directly concerned in the contraction of muscle, but as occurring in all parts of the body. They may be regarded as a slow combustion in which complex substances full of latent energy are reduced to simpler stable conditions with less or with no latent energy. Like St. Paul, the animal, says Dr. Foster, "dies daily." "All the inner labour of the body, both that of the chemical gland-cells, of the vibrating nerve-substance with its accompanying changes of consciousness, and of the beating heart and writhing visceral muscles, is, sooner or later, by friction or otherwise, converted into heat; and it is as heat that the energy evolved in this labour leaves the body." Only as heat or as motion of limbs, jaws, &c., does the energy set free in the animal body make itself externally apparent. This combustion and degradation of material necessitates new supplies, and hence we have the phenomenon of the inception of food and the chemical processes connected with it.

The Problems of Physiology are then stated as the result of the preceding survey of the actions of a living being to be as follows:—(1) To discover the laws of transmutation of complex unstable food into still more complex living flesh, and the laws by which the latter breaks down into waste products, void of energy. (2) To discover the laws of the origin of nervous vibrations, of their passage to and fro in nerve substance and of their ultimate disappearance in connection with muscular contraction or otherwise. (3) To discover the laws of how the energy of chemical action is transmuted into and serves as the supply of that vital energy which appears as movement, feeling, and thought.

This rough analysis of the problems of physiology is "the residue of many successive phases of opinion." It is in tracing the influence of these successive phases and estimating the value of their residues that the skill of Prof. Foster is most successfully exerted. Such an appreciation of the historical significance of the various factors of his science, should, we think, be as much the indispensable possession of a cultivated specialist as is a knowledge of his country's political history to the statesman.

The exigencies of life, Dr. Foster tells us, early directed man's attention to the phenomena of the animal body and thus brought the study of physiology to the front before its time. Hence in the absence of the knowledge of physics and chemistry, explanations were assigned to those phenomena of animal bodies which were not obviously identical with those of inanimate bodies, under the names "vital spirits" and "animal spirits." In the seventeenth and eighteenth century, however, the progress of anatomical knowledge led to the perception of the fact that the animal body contained, if it did not actually consist of, a number of mechanical contrivances each of which could be shown to perform some service in the animal economy for which its construction especially fitted it. In this way grew up the doctrine of "organs" and "functions," and it was held that the inspection of structure was sufficient to enable an acute observer to determine the particular function of any given part. Great progress was made under the influence of this doctrine—the most notable example of its triumph being the discovery by Harvey of the function of the heart and the mechanism of the circulation of the blood. The doctrine of vital and animal spirits still survived as giving an explanation of the motive force which set the complicated machinery of connected organs at work.

In the physiological "cell-theory" of Schleiden and Schwann the adequacy of the doctrine of organs and functions to explain the phenomena of life, whilst apparently finally established, received, according to Dr. Foster, its death-blow. It appears to us that Dr. Foster does not quite give its true significance to "the cell-theory." It is true that the founders of that theory attached undue importance to the structural characters of the cell. But Schwann at any rate attached the greatest importance to the cell-substance, and to its molecular and atomic constitution, and the doctrine that function is dependent on structure, when by structure we understand not merely coarse visible structure, but molecular structure, which differs in any two cases by a difference of internal movement of molecules rather than by a difference of their permanent position—this doctrine is triumphant to-day, and is proclaimed in that portion of the present article which treats of different kinds of protoplasm.

A quotation is given from a well-known article by Prof. Huxley, written thirty years ago, in which it is stated that cells "are no more the producers of the vital phenomena than the shells scattered in orderly lines along the sea-beach are the instruments by which the gravitative force of the moon acts upon the ocean." Apparently Dr. Foster thinks this statement to be defensible even to-day, but the conception of living matter and of the significance of cell-substance and structure thus indicated appears to us to be more difficult to reconcile with the modern doctrine of protoplasm than is the doctrine of Schwann, which, to use his own words, was "le contraire de la théorie generalement admise pour les animaux, d'après laquelle une force commune construit l'animal à la manière d'un architecte," and which argued from the uniform construction of organisms by modification of the nucleated corpuscles called cells that "c'est partout la même force qui reunit les molécules en cellules, et cette force ce ne pouvait plus être que celle des molécules ou des atomes; le phénomène fondamental de la vie devait donc avoir sa raison d'être dans les propriétés des atomes"—that is to say, in the atoms of the substance of which the cells consist which has now received the name protoplasm.

Dr. Foster next gives a vivid picture of the importance of the discovery by Claud Bernard of the glycogenic function of the liver—a function which could not be inferred from the inspection of the liver either macroscopic or microscopic. Such discoveries as these led to the recognition of the existence of most important processes or "functions" in the animal body which had no correlative in visible structure. Thus physiologists were led to see in the mind's eye the invisible structure of cell-substance and the "protoplasm theory" obtained its foundations.

A brief survey of the life of a corpuscle of protoplasm as exemplified in an Amœba follows, and attention is directed to the *constructive* and *destructive metabolism* going on in the substance of such an organism. There are anabolic and katabolic changes in that substance, which may be compared to a double flight of stairs leading up to and down from a hypothetical summit; that summit is what we mean by protoplasm, but whether the term should include a few of the steps up or down or be limited to the top plane cannot at present be decided.

This protoplasm of the unicellular organism exhibits properties which may be classed as (1) *Assimilation;* (2) *Contractility;* (3) *Irritability* or *Sensitiveness.* From the consideration of these we are led on to that of a simple multicellular organism—a Hydra—in which a first stage of differentiation of these properties between two groups of cells—the endoderm and the ectoderm—is observed. Then in due course the further differentiation of these two primary groups of cells in a higher animal is traced—in an account of the organs and tissues with their specialised properties and functions derived by gradual modification from the lower stage of differentiation.

The relation of the complex organs, composed of numberless cell-units, of a higher organism to the practically homogeneous protoplasm of a single cell-corpuscle having thus been traced, Dr. Foster takes one organ of a higher animal—the kidney—as an example of the problems which present themselves to the modern physiologist. There are, he points out, two points of view, two aims of inquiry which pursue in many respects different methods, though ultimately blending and tending conjointly to the explanation of the action of the kidney. They are distinguished as the "mechanical" and the "molecular," and correspond in these later days to the earlier and later standpoints of physiology represented by the doctrine of organs and the doctrine of cell-substance. The physiologist's inquiry is sketched from the first point of view, and it is pointed out that this inquiry "takes on to a large extent the characters of an attempt to unravel an intricate game, in which the counters are nervous impulses, muscular contractions, and elastic reactions, but in which the moves are determined by topographical disturbances and mechanical arrangement." The second kind of physiological inquiry into the kidney ignores for the time being these grosser conditions, and is directed to the molecular action of the protoplasmic cells which build up the distinctive structure of the kidney, namely, its tubules.

Reverting to "a brief survey of the whole field of physiological inquiry," Dr. Foster says:—"The master tissues and organs of the body are the nervous and muscular systems, the latter being, however, merely the instrument to give expression and effect to the motions of the former. All the rest of the body serves simply either in the way of mechanical aids and protection to the several parts of the muscular and nervous systems, or as a complicated machinery to supply these systems with food and oxygen, *i.e.* with blood; and to keep them cleansed from waste matters through all their varied changes."

That, no doubt, is true if the organism be viewed as an individual and not from the point of view which regards the individual as one of a race and the race as part of the general outcome of organic development, and this as again a part of a more general phenomenon. The biologist who takes his stand on the doctrine of evolution must, we venture to think, regard as the "master-tissue" over and above those indicated by Dr. Foster—the reproductive tissue or the specific cells of the ovary and testis. It is in every animal this little nest of germ-plasma handed on from generation to generation with scarcely a change which receives the homage and service of all the various products of differentiation of its brother-cells. The latter are but the carriers, protectors, and servants in the struggle for existence of the undifferentiated germ-plasma—even the cells concerned in thought and reason exist but to protect the germ-cells. The former perish as a mere husk whilst the germ-plasma is immortal; it forms, by growth and fission, on the one hand, new germ-plasma which never dies, and on the other hand protecting tissue-cells, which have only an evanescent existence. As Dr. Foster himself has elsewhere said:—"The animal body is in reality a vehicle for ova, and after the life of the parent has become potentially renewed in the offspring the body remains as a cast-off envelope whose future is but to die."

In the latter part of the article our present knowledge of the nature of protoplasm, and of the processes which go on in connection with it, is forcibly sketched. Different *kinds* of protoplasm are recognised, the differing qualities of which are to be regarded by the biologist as "the expression of internal movements" of the molecules of the protoplasm. The term "mesostate" being used to express those ascending and descending steps of the pyramid whose summit is protoplasm, and "anastate" and "katastate" corresponding respectively with those constituents of cell-substance which are on their way to attain, and those which are falling away from the state of perfect protoplasm, we find that the tendency of inquiries into the molecular processes taking place in living secreting cells, in muscular tissue, and in the various forms of nerve-tissue, "is to lead us to regard the varied activities of these tissues as due to molecular disruptive changes in their several katastates, these being various stages of the downward metabolism or katabolism of protoplasm."

Hering's recent speculations on the relation of colour sensations to the condition of the protoplasm of the percipient cells lead, Dr. Foster thinks, to a new molecular physiology. He gives us the hope that by an application of Hering's conceptions (which the limits of our space do not permit us to notice more fully) to other groups of protoplasmic units a new departure may be effected, and that we may look forward to a very great advance in our knowledge of the nature of the processes taking place in living cells.

Dr. Foster concludes his article with an outline of the methods of physiological inquiry and an unanswerable though brief exposition of the dependence of the progress of physiology upon experiment on living organisms.

The article on Pianoforte is of considerable interest for several reasons; first, because it is signed with the initials of Mr. A. J. Hipkins; secondly, from the number and felicity of the illustrations; thirdly, because it takes up a special and somewhat neglected point in the history and development of the remarkable instrument which has superseded the far more ancient organ, and which has become the domestic companion and indispensable accessory in thousands upon thousands of households throughout the civilised world.

Probably no man living knows so much about the pianoforte as Mr. Hipkins: attached for many years to the honoured house of Broadwood and Sons; almost able to remember its original title of Tschudi and Broadwood, which carries us back at one bound to the epoch of the harpsichord Mr. Hipkins is not only an experienced musician, but an excellent physicist in his special line. He has read valuable papers before the Royal Society, and efficiently co-operated with Mr. Alex. Ellis in his laborious determinations of pitch and of oriental or archaic musical scales.

The somewhat neglected subject here given with the terseness and accuracy of a monograph, as is proper in a work somewhat of the nature of an index, is the mechanical development of the modern pianoforte from the earliest form of keyed instrument with strings, shown in a drawing by Miss Edith Lloyd of a sculpture in St. Mary's Church, Shrewsbury belonging to the first half of the fifteenth century. Besides this and other woodcuts of typical instruments, is a series of diagrams showing the various forms of "tangent," "jack," "hammer," "action," and "escapement" by which the sounding string has been successively made to vibrate with ever increasing fulness and beauty of tone and quality. Towards the end of the article the recent substitution of metal for wooden framings is similarly summarised and illustrated. No doubt much of this would be hard reading for an unmechanical student; but it was really needed, and as a compact whole could hardly be said to exist previously.

The early part of the article appeals to every reader, and is full of fascinating and original research. There are eleven other capital woodcuts besides that named above of clavichords, clavicymbalums, spinetts, and clavicytheriums, which, under a multiplicity of names, preceded the four "gravicembali col piano è forte," which Cristofori, the Paduan harpsichord maker had, on the undoubted authority of the Marchese Scipione Maffei, completed in the year 1709. This date may be looked on as the birthday of the name and the instrument. Originally adjectival and explanatory, it has been adopted substantivally wherever this ubiquitous form of the "dulcimer with keys," as Mr. Hipkins quaintly defines it, has penetrated.

BALL'S "STORY OF THE HEAVENS"

The Story of the Heavens. By Robert Stawell Ball, LL.D., F.R.S., Royal Astronomer of Ireland. (London, Paris, New York, and Melbourne: Cassell and Co., Limited, 1885.)

POPULAR works on astronomy, either on its entire range or selected portions, have been so numerous of recent years as to make it difficult to judge a new one entirely on its own merits; it is felt that there must be some well-marked originality of plan or execution, some novelty of treatment, or freshness of fact, to justify an addition to an already abundant literature.

The present work can urge its claim to a favourable reception on a twofold ground; it is the fullest and most complete exposition of the leading facts and principles of astronomy which has yet been laid before the entirely unscientific public, and it devotes special attention to some of the most recent and interesting astronomical discoveries. It is in no sense whatsoever a student's book, but aims to give, in such simple and untechnical language as may be most acceptable to the general reader, a comprehensive view of the results of astronomy as at present received. So thoroughly is it elementary in character that Dr. Ball from time to time seems to think he has a childish audience before him, and descends to a style which is nowadays considered almost too condescending to be addressed even to children. Thus, in speaking of the distance of the sun, he says (p. 28):—

"The actual distance of the sun from the earth is about 92,700,000 miles; but merely reciting the figures does not give a vivid impression of the real magnitude. 92,700,000 is a very large quantity (*sic*). Try to count it. It would be necessary to count as quickly as possible for three days and three nights before one million was completed; yet this would have to be repeated nearly ninety-three times before we had even counted all the miles between the earth and the sun."

But though Dr. Ball may sometimes resort to this infant-school style he never falls into the opposite fault of being turgid or obscure. His language is always clear and distinct, and when treating of the particular subjects most congenial to him he usually succeeds in avoiding the fault we have just noticed, and his style leaves nothing to be desired.

In a brief introduction Dr. Ball indicates the principal questions which it is the business of the astronomer to seek to answer, and glances at some of the most important discoveries made by the ancients, concluding with the labours of Copernicus. The main volume then commences with a chapter on the astronomical telescope. The Dunsink South equatorial, the great Vienna refractor, and Lord Rosse's 6-foot reflector are described, and illustrations given of them; the Paris meridian circle is represented as a type of meridian instruments, and a well-written page (p. 22) is devoted to drawing a contrast between the ideal instrument and the actual one.

A number of chapters on the different members of the solar system follow. These occupy more than half the volume, and do not call for much special comment, for, whilst travelling over such well-trodden ground, there is but little scope for original treatment. The author throughout gives a clear matter-of-fact account of what he has to describe; there is never for a moment any difficulty in following his meaning, and for a work of this character this is a first essential. The chapter on the Sun is perhaps the least successful. Dr. Ball considers that it is not proved that "sun-spots are really depressions in the surface"; a statement which may be perfectly correct if "proved" is to be taken in its hard mathematical sense; but it ought to be supplemented by the further one that the entire evidence is in favour of that supposition. No reference is made to the frequently-repeated coincidences of solar outbursts and magnetic disturbances which were observed in 1882 and 1883, and which placed the connection of the two orders of phenomena in such a striking light. And again with reference to the spot-cycle, the nature of the cycle is rather crudely stated, and one of its most curious features—the change of latitude in the *locale* of the spots—is altogether unnoticed. Chapter III., on the Moon, contains a little sketch-map of the moon and descriptions of the most striking formations. The laws of eclipses, the use of the moon in navigation, and Nasmyth and Carpenter's theory of the volcanic origin of the lunar craters are treated of with the author's usual clearness and at considerable length. In the concluding paragraphs Dr. Ball expresses his belief that forms of life unknown to us may probably exist on many of the celestial bodies, and applies to the question of the plurality of worlds the lines of Tennyson :—

> "This truth within thy mind rehearse,
> That in a boundless universe
> Is boundless better, boundless worse."

The fourth chapter deals with the solar system as a whole, with the detection and identification of planets, with the positions and dimensions of their orbits and their own comparative sizes. It is followed by a chapter on the Law of Gravitation, a most important one, and admirably written. The law of gravitation is so important in itself, and so little understood by the unscientific portion of the public, that such an explanation as is here supplied is much needed.

The succeeding chapters deal with the planets one by one, beginning with Vulcan, the "Planet of Romance," which Dr. Ball is inclined to believe was really seen by Prof. Watson during the total solar eclipse of 1878, on the not unreasonable ground that an observer of his experience and skill was not likely to have been mistaken. In the chapters on the other planets the points to which most attention has been paid are the descriptions of the various modes of determining the sun's distance, and the size, form, and weight of the earth. There is a pleasing and somewhat full biography of the elder Herschel in the chapter on Uranus, and the wonderful story of the discovery of Neptune is told again in a fresh and engaging style. Leaving the regular members of the solar system, we come to the comets and shooting-stars, and with these Dr. Ball begins to treat his subject in a somewhat more original manner, and there is very much to commend in these and the following chapters. Encke's comet, the evidence it affords as to a resisting medium, and its usefulness as a means of determining the masses of Jupiter and Mercury and the distance of the Sun, occupy a considerable space. Bredichin's theory of comet's tails is clearly explained. Dr. Ball is, however, scarcely correct in authoritatively classing the great comet of 1843 as a non-periodic one, and the similarity of its orbit to those of the great comets of 1880 and 1882 surely deserved a word of notice. In the chapter on shooting-stars he draws a sharp distinction between meteors and meteorites, and expresses his conviction that Prof. Newton was wrong when he spoke of a meteoric stone as having probably been part of a comet. He also broaches and supports by some ingenious reasoning the idea that meteorites are largely of terrestrial origin, and he points out that meteorites of iron are much less frequent than those of stone.

Chapter XVIII. is on "The Starry Heavens," and is especially commendable for the series of little diagrams in which the relative positions of the principal fixed stars are shown with admirable distinctness. Nothing can be easier than for the reader with this portion of the book in hand to make himself acquainted with the general configuration of the northern constellations. Several instructive points are well brought out in the two following chapters, but in Chapter XXI., on the Distances of the Stars, we find Dr. Ball on ground which he has largely made his own. Herschel's attempt to form a conception of the distribution of the stars in space is clearly explained, and made the basis of a detailed description of the method of determining the distance of a star by its annual parallax, and the cases of 61 Cygni, α Centauri, and Groombridge 1830 are dealt with at considerable length. The difficulties of parallax work are sympathetically described, and the drawback often experienced of a long series of observations failing to show any parallax at all is made the occasion for enlarging on a particular instance of such a failure, viz. Nova Cygni, 1876. The chapter concludes with an explanation of Herschel's discovery of the motion of the solar system towards the constellation Hercules. The spectroscope is much more sparingly dealt with, and the entire range of astronomical spectroscopy is despatched in one of the shortest chapters in the book. It is not possible that so condensed an account should be very thorough or complete, but, given the necessity to confine the subject within these limits, it is difficult to see how it could have been much better done.

The three following chapters deal with Star Clusters, and Nebulæ, Precession and Nutation, and the Aberration of Light. Each of these subjects is well handled; the explanations of the three kinds of apparent motion shown by the stars being clearly and carefully explained, without going into any details which would be likely to prove too abstruse or tedious for any ordinary reader. The chapter on Nebulæ is illustrated by three plates, one of which, Trouvelot's drawing of the Great Nebula in Andromeda, is very well executed.

The two concluding chapters are of especial interest. Chapter XXVI., on "The Astronomical Significance of Heat," deals with the most important points in the history and method of the evolution of the solar system; the presence of heat in the body of the earth, the law of cooling, the heat of the sun and its possible sources, the doctrine of energy, the nebular theory and the evidence which supports it. With respect to this last it should be observed that the old illustration of the trees in the forest is by no means very apposite. Dr. Ball is, however, careful to distinguish such a theory, however magnificent and attractive, from the truths of astronomy properly so called.

From nebular evolution we pass naturally to tidal evolution. It is but comparatively recently that Dr. Ball's lecture upon this subject was reported in these pages, so that it is only necessary to say that the romantic story is well told this second time. The criticisms to which the theory was subjected are not referred to here, though some deserved greater consideration than to be silently passed over.

As we have already said, this is in no sense whatsoever a student's book. Dr. Ball has already shown how well qualified he is to produce such a work when he desires to do so, but he has had an entirely different purpose here. It may be doubted whether he has not in some instances been too general and undefined in his mode of treating his subject; the explanation of the principles and methods involved in the determination of the sun's distance by means of Transits of Venus, for example, is particularly meagre and unsatisfactory. The public that does not care to have to exert much thought over its reading is not the public that will purchase books on astronomy 550 pages in length; an occasional light article in a magazine will satisfy its utmost craving.

Nevertheless a book which in a lucid and easy style supplies accurate and the latest information as to the methods and discoveries of astronomy, which is written by a competent authority, and which, if not profusely illustrated, is supplied with plates and woodcuts which leave no important object unrepresented, no fundamental argument unsupported, can only be spoken of as a good one; and those who wish to possess a full, interesting, and popular account of the present state of the most noble and enthralling of all the sciences cannot do better than make themselves possessors of the "Story of the Heavens."

OUR BOOK SHELF

Annual Report of the Board of Regents of the Smithsonian Institution for the Year 1883. (Washington: Government Printing Office, 1885.)

THIS is the most bulky, and perhaps the most valuable, of these well-known Reports; it consists of very nearly 1000 pages, and we learn, from the resolution of Congress which precedes it, that 16,060 copies have been printed. The more strictly official part of it deals with the Smithsonian Institution and the Natural History Museum, including the Report of the Committee on the Henry statue recently erected in the grounds; but, besides these, we have Reports on the various branches of science, so valuable that no scientific library should be without them. Astronomy has been taken in hand by Prof. Holden, the newly-appointed Director of the Lick Observatory; meteorology, by Mr. Cleveland Abbe; physics, by Prof. Barker; zoology, by Prof. Guild; and anthropology by Mr. Otis T. Mason, the latter covering nearly 200 pages. Other branches of science besides those which we have named are reported at less length.

When we consider the importance of these *résumés*, and the fact that 7000 copies of the volume are being distributed gratuitously by the Institution all over the world, we may readily concede that in this, as in their other duties, the Regents of the Institution are faithful to the trust imposed upon them by Smithson to promote the increase and diffusion of knowledge among men.

The Sun: a Familiar Description of His Phenomena. By the Rev. Thomas William Webb, M.A., F.R.A.S. (London: Longmans, 1885.)

THIS is a little book of seventy-eight pages, containing what appears to have been a lecture given by the author, who, to the great loss of observational astronomy, died a short time ago. That part of it which deals with the telescopic facts is very much more in harmony with our present knowledge than that smaller part of it which deals with the revelations of the spectroscope. The whole is very charmingly and simply written.

Notes on the Physiological Laboratory of the University of Pennsylvania. By N. A. Randolph, M.D., and S. G. Dixon. (Philadelphia, 1885.)

THIS little volume consists of a series of short papers giving the results of practical investigations into the behaviour of certain substances, such as starch, cod-liver oil, boiled and unboiled milk, &c., when used as articles of food by infants and adults. Many of the papers are of interest; all of them show evidence that in the University of Philadelphia, physiology is not taught as a matter of book-learning, but that the students are instructed in the practical bearings of the science.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Lieutenant Greely on Ice

I HAVE read with deep interest the graphic but brief account of Lieut. Greely's Arctic explorations given in NATURE of November 26 (p. 90), and also in some of the Scottish papers, which touch upon subjects not mentioned in NATURE.

Assuming that these reports are, in all material points, correct, I ask leave to be permitted to offer some remarks on a few of the opinions expressed by the distinguished explorer, the correctness of which seems open to question.

Before doing so, however, I would draw attention to the very considerable difference in the mean yearly temperatures at Discovery Bay, as given by the English Government ship that wintered there in 1875-76, and that of Lieut. Greely wintering at the same place six or seven years later.

Capt. Stephenson, H.M.S. *Discovery*, 1875-76 ...	$-4^{\circ}\cdot23$ F.
Lieut. Greely, in house six or seven years later, about	$+4^{\circ}\cdot00$
Making a difference of	$8^{\circ}\cdot23$

I suppose the thermometers to be in both cases correct, and the mean temperatures computed in the same manner in each case. In saying that "Grinnell Land has the lowest mean temperature in the globe," surely Lieut. Greely goes a little too far, as no observations have elsewhere been made in so high a latitude, nor at any point in the great circle of 1100 miles' diameter *nearer* to the Pole than Discovery Bay, in nearly all parts of which it would be a very natural conclusion to arrive at, that the mean temperature would be lower. Lieut. Greely adds, "This" (the lowest temperature in the globe) "was in accordance with their expectation."

Kane went to the Arctic Sea with "expectation" and a belief that he would find an open Polar sea! His steward, Morton, conveniently found it for him, and it was *believed* in for a time, until other expeditions passed the place where "Morton's pool" of open water had been seen; but alas! not a trace of it could be found, although ships had gone by, creeping along shore, some hundred miles further north. The distinguished Greenland explorer Rink, finally, effectually demolished this Arctic dream. Lieut. Greely's open Polar sea of 1100 miles' diameter round the Pole seems to be a myth of a somewhat similar kind. It is purely a theory, with facts, to my mind, adverse to its probability; for why this immense body of water in the far north, whilst constantly sending forth great ice-streams southward through the broad inter-Greenland-Spitzbergen Channel, should be itself ice-free, whilst other seas far southward, having a much higher temperature, and probably with currents and gales of wind at least as strong, are ice-encumbered, is rather difficult to understand.

As regards floebergs, Lieut. Greely has advanced their size and thickness far beyond anything one would infer from reading the narrations of the English Expedition of 1875–76, which first gave the name to those curious masses of ice. He has not only done this, but he attributes their formation to a source which completely destroys the meaning of the name "floeberg," used in contradistinction to "iceberg," to show that the former has its origin from the floe or sea ice, instead of from ice formed on land, and is either built up by the gradual increment of the floe and the snow that falls upon it, or, as I believe more likely, by a number of floes being forced by immense pressure one over the other, until great thickness is attained. Perhaps the best example of a floeberg (according to my idea) that I can give, is that which lifted the ship of the Austrian Expedition seventeen feet (I think) out of the water, became a great floating mass of ice in a week or less, a mile in extent and of great thickness, and carried those good explorers Weyprecht and Peyer helplessly about for a long time in 1873-74, in Barentz Sea, then landed them safe on one of the Francis Joseph Islands; thus leading to the discovery of this great Northern land. Snowdrifts would in the course of one winter (I have seen a fifteen feet depth of drift in one night) fill up most of the inequalities of surface, and thus the floeberg is complete.

Lieut. Greely says that these "floebergs are simply detachments from slowly-moving glacial ice-caps, from an ice-covered land in the neighbourhood of the Pole;" that "Dr. Moss (of the *Alert*) was certainly correct as to the universality of stratification in this *ancient* ice, and he concurred in the Doctor's opinion, that its salinity was due to efflorescence and infiltration."[1]

First as to the formation of these floebergs; Lieut. Greely tells us they are detached from an ice-cap 1000 to 4000 feet thick near the Poles. Surely if this were so, some of these great masses, which would show about 140 feet above water, would have been seen by Parry, when in the summer of 1827 he was in lat. 82° 45′ N. (only thirty-nine miles south of Greely's extreme) to the north of Spitzbergen; but neither Parry nor any of the brave whaling captains, who have gone to high latitudes between Greenland and Spitzbergen—the great highway of northern ice in its southward drift—have ever seen anything of the kind.

In the Antarctic we all know that such ice-mountains (the source of which Sir James Ross's discoveries tell us of) drive down to lat. 60° S. near to Cape Horn; the natural idea is, that they would do the same thing in the Arctic Sea—in company with the great ice pack, through the wide high road above mentioned—and not confine themselves to the coast seen by Lieut. Greely's party.

A word or two on my own experience much further to the south. When passing in my boats for 800 or 900 miles along the west shores of Hudson's Bay in 1846 and 1853, I saw several floebergs aground, some thirty or forty feet above the surface, so large and high that any one at a distance of a mile or so, would have mistaken them for true icebergs; they were merely a mass of floes forced together by strong winds. In such low latitudes (58° to 66°) these spurious icebergs all disappeared before autumn.

No true iceberg that breaks away from land-ice is ever found, as far as I know, to contain saline strata, as the late Dr. Moss found to be the case with the floeberg from which the crew of the *Alert* in 1875-76 took the ice, for drinking or making tea. Sometimes this ice was so salt as to be unfit for the purpose, although high above the sea-level. This result is attributed by both Dr. Moss and Lieut. Greely to "infiltration." I cannot understand how saline fluid could "infiltrate" *upwards* from the sea into ice—a solid—in which there would be no pores through which it could flow, apart from the fact of the greater specific gravity of the brine.

I do, however, know from personal experience that saline fluid does, under certain circumstances, percolate or filtrate *downwards*, converting sea-ice, previously saline, into a sufficiently fresh state to afford good drinking-water when thawed. This discovery, like a good many others of more importance, was accidental. In passing a piece of old ice—that is, of a former year's formation, which was known to be so by its wasted and rugged outline, as it stood some feet above the surrounding level ice-floe—I knocked a small piece off, and on putting it into my mouth, found it quite fresh. From that time, during sledge journeys of 1200 miles in the spring of 1847, I looked out for some old rough ice, before building our snow-hut for the night's shelter, so as to get water quickly.

Experience had taught me that a kettleful of water could be obtained much more rapidly and at a far less waste of fuel by thawing ice than from snow, because the latter, however closely packed, contained much air, which, at a temperature of zero or lower, required extra fuel to warm it *up* to 32° Fahrenheit; a kettleful of snow will give little more than a third of a kettleful of water, whilst the same measure of ice will nearly fill the kettle with water.

The fresh ice I speak of could not be part of an iceberg, because there were no bergs in the great bay where we were travelling. Moreover, if a piece of this ice (which was fresh at a few feet above the sea-line) was chopped off on a level with or below the water-line, it was found to be saline.

How does this take place? Simply, I imagine, by the brine or saline fluid filtrating downwards through pores made by itself in the ice, as soon as the summer temperature became high enough to thaw the saline part, the fresh portion retaining its solidity, with the exception of the minute pores worn out as above described.

My belief is that the floebergs seen, and so named by the English Expedition of 1875–76, were formed of saline sea-ice, piled one floe over another, and that when the summer temperature penetrated them to a certain extent, the salinity filtered downwards as above described, but that certain layers or strata, either from not being subjected to a sufficient rise of temperature or from some other cause, still retained their saltness.

All sea-ice has a surface-layer, more or less thick, of brine efflorescence, far more saline than the body of the floe. If, then, six or eight floes are forced up, the one over the other, there will be so many layers of these thin very saline strata.

I repeat that infiltration *upwards* in this case is contrary to all aws of gravitation, unless those learned in chemistry or physics can show that there is some powerful attraction or affinity to drag a saline fluid upwards through a dense solid.

This communication has gone far beyond the limits I intended, and yet is very short of what might be said on other parts of Lieut. Greely's lectures in Scotland. I must conclude by expressing my admiration of the great amount of geographical work done by this expedition, and the miraculous rescue of the few survivors where twenty-four hours' delay would have been fatal, resembling in this respect very closely the rescue of a *part* of a Government overland expedition in Arctic America sixty-four years years ago, who, but for the arrival of friendly Indians with food and most tender nursing of them, could not have lived more than a couple of days longer.

4, Addison Gardens, Kensington, Nov. 28 JOHN RAE

P.S.—The *Scottish Geographical Magazine* has just reached me, by which I find Greely's mean temperature of his winter quarters to be −4° F. instead of +4°, therefore almost exactly the same as the temperature found by the English Expedition of 1875–76, instead of there being 8° difference—as I put it.—J. R.
December 7

[1] I met the late Dr. Moss at the British Association when held some years ago in Dublin. We conversed a good deal on the above subject. I learnt from him, if my memory is correct, that the floeberg from which the crew of the *Alert* took the ice to thaw for their use, was found to have strata too saline to drink. This explanation I think requisite.—J. RAE.

The Recent Star-Shower

IT being important to ascertain the duration of the recent shower of Andromedes, observations were continued here on the night of November 30. During a watch maintained for about four hours and a half between 5h. 30m. and 10h. 15m., ten Andromedes of most certain character, together with two other meteors, in reference to which some doubt existed as to their absolute identity with this stream, were recorded from a radiant-point carefully determined at $21° + 42\frac{1}{2}°$. Thirty-one non-conformable shooting-stars were also seen from showers in Perseus and the region eastward.

It is therefore clear, from the results obtained on November 30, that the display had not lost its visible character, though it had evidently subsided into a state of great feebleness. It yielded certainly not more than three meteors per hour for one observer, and these were extremely faint.

On the evening of December 1 the sky was again clear. A prolonged watch of the region of Andromeda then revealed no trace of the display. Meteors were very rare, generally, all the evening. On December 4 they were very frequent, but the radiant-point near γ Andromedæ gave no sign. The ζ Taurids and Geminids (which are specially mentioned in the current number of NATURE (p. 108) as deserving observation during the present week) were both visible, and a number of contemporary streams had come actively into play. But, during long watches on the nights of December 1 and 4, there was no appearance of outlying Andromedes. The cessation of the shower definitely occurred between November 30, 10h. 15m., and December 1, 5h. 45m., after an *observed* duration of little more than five days. But this period unquestionably fails to represent the real duration, for, could observations have been made before moonrise on the early evenings of November 24 and 25, there is no doubt it would have been detected. We can hardly admit a sudden rise of the shower from invisibility on the 25th to a degree of richness on the 26th sufficient to give more than 100 meteors per hour. It is to be hoped that reports from other stations will throw some light on the visible development of this remarkable stream. In any case the extremely narrow limits of its display on November 27, 1872, offers a strong contrast to the comparatively prolonged duration observed at its recent return.

Bristol, December 6 W. F. DENNING

WHILE watching the meteor shower of the 27th ult. I observed what closely resembled the appearance of an aurora. There was seen extending along the horizon from about south to about west-north-west—perhaps further towards the north, for my view was there obstructed—and upwards for about 20° from the horizon, a faint reddish-pink luminous haze, varying fitfully in colour, becoming sometimes nearly white, and in intensity both as regards time and position. The greatest brightness noticed by me was nearly due south. Stars were clearly visible through it.

On referring to the letters in NATURE upon the shower of November 27, 1872—to refresh my memory upon other points—I found that appearances of an aurora on that evening are recorded by "several correspondents." [Mr. Denning's letter in NATURE, December 5, by Father Denza in Piedmont (NATURE, December 19), by Mr. Baber at Liverpool (same number), and the Hon. Mr. Newton and Mr. Bruce at Mauritius ("a pulsating coruscation, similar to the appearance of the aurora australis"), NATURE, January 23, 1873]. NATURE for January 16, 1873, contains a letter recording a "pale auroral light" seen at the same time as a shower on December 7, 1838, and Mr. Denning (April 24, 1873), records that the April shower was accompanied by "bright displays of auroræ."

Mr. Newton and Mr. Bruce add that "the instruments at the Observatory gave no indication of a magnetic disturbance."

Some of your readers may be able to say whether any magnetic disturbance was observed on the evening of the 27th ult. I saw the auroral appearance about 7.15 p.m.

Rugby, December 7 J. B. HASLAM

P.S.—In a note received to-day in answer to my inquiry, the Superintendent of the Kew Observatory kindly informs me that at Kew the "magnetic curves for horizontal intensity, vertical intensity, and declination were remarkably steady throughout the whole of the 27th and 28th ult., being almost straight lines at the time of the meteoric shower." He adds that no auroral effects were seen at Kew.—J. B. H. (Dec. 8.)

IN case England has been clouded on the 27th, it may be well to state that the meteors were brilliantly seen in the Adriatic. A few were visible on the night of the 26th; on the 27th, at 16h 30m. G.M.T., they averaged thirty per minute; at 17h. they had much increased, and were counted, at 18h. 10m., at seventy per minute, while at 20h. 40m. they had decreased to thirty per minute again; on the 28th very few were seen. During the rapid shower they were not equally distributed; for six or eight seconds only one or two were to be seen, and then, in a couple of seconds, perhaps eight would be counted, mostly seen simultaneously. The radiant-point was estimated at about 15° S. of the following end of Cassiopeia at 16h. 30m., and at about 3° S. of the preceding end at 20h. 40m. The trails were more persistent and brilliant in the latter part of the evening. One was distinctly seen by two observers to sharply bend its apparent course about 20°, possibly a case of perturbation by a non-luminous meteor, or else of splitting. A large number were as bright as first-magnitude stars, and many equal to Venus. WM. F. PETRIE

s.s. *Tanjore*, November 28

FROM the accounts in NATURE and in the *Times*, it is evident that the display of meteors was much finer in the east of Switzerland than any of those mentioned by your correspondents. My attention was first directed to the shooting-stars shortly after 6 o'clock (local time here being about thirty-eight minutes in advance of Greenwich time). For half an hour after that time the fall was continuous, several meteors appearing together. In fact, so many were falling, that it seemed to me hopeless to attempt to count them, but I should think that they must have fallen, on a moderate computation at that time, at the rate of at least 200 a minute. Many of them were especially brilliant, and those falling near the mountains, which completely encircle this village, produced, I presume by irradiation, the curious appearance of passing between the spectator and the mountains. The richest period of the display when, looking from a window, four or five were seen together in one part of the heavens did not last for more than an hour, but the phenomenon continued with less effect until 9 o'clock, when the sky which, until that time had been perfectly clear, became overcast. The height of the high-lying plateau of the Canton Grisons, more especially in the Engadine, and the remarkable absence of aqueous vapour, causes many more stars to be visible here than in the denser air of England, and this, no doubt, in large measure, accounts for the superior brilliancy of the display as witnessed here. This strangely affected the imagination of some of the peasants of this village, one young woman in particular spent the evening in tears and lamentations, momentarily expecting the end of all things. J. F. MAIN

Wiesen, Canton Grisons, Switzerland

"Evolution without Natural Selection"

TWO or three points in Mr. Romanes's letter in your issue of December 3 (p. 100), leave me no other alternative than to again ask you to insert the following few remarks. I beg to inform Mr. Romanes that with Darwinism my book has very little to do. It neither attempts to refute nor confirm the Darwinian hypothesis of Natural Selection. Neither is it an "emendation of Darwinism"; but the facts it contains seem to be an all-necessary supplement to the great naturalist's hypothesis. It is to be regretted that at the present time so many naturalists accept the theory of natural selection as an exclusive explanation of the evolution of existing species. They unconsciously blind themselves to the existence of any other agent in the work of evolution. To them there can be, nor is, no other. No greater error could be made; and it is my firm conviction that as time goes on the theory of natural selection will gradually lose much of its present presumed universality. What is becoming more evident every day is that existing species do not owe near so much to natural selection for their evolution as extreme Darwinians would have us believe. What the remote ancestors of these species derived from its influence is another matter. How far its influence has been exerted on living forms is not for me even to conjecture; but certainly, so far as birds are concerned, the evidence of its influence is astoundingly slight in comparison with the number of species.

I am very pleased to see that Mr. Romanes has changed his opinion concerning "trivial specific characters," and now admits that they are both numerous and important. But they cannot even be regarded as "insignificant" as compared with the great "organising work of natural selection." For, according to the Darwinian theory, they should owe their very presence to its influence, but, unfortunately for the hypothesis, they do not. Once more I must strongly protest against Mr. Romanes saying that my book attempted to explain the *cause* of variation. It does nothing of the kind. Nor do I consider it fair for Mr. Romanes to infer that isolation, &c., do not explain the cause of variation, and therefore that they fail as evolutionistic agents. It would be just as fair and logical to say that the Darwinian hypothesis is a failure because it does not explain the cause of variation. Darwin must have a variation to begin with for natural selection to work upon; so must isolation. The cause of variation is one of the greatest secrets which Nature still retains in her keeping; but doubtless it will soon be wrested from her.

London, December 6 CHARLES DIXON

I HAVE not changed any of my views; but Mr. Dixon appears to change his within the limits of two consecutive sentences. For, immediately after his strong protest against my statement that he has attempted to explain the causes of variation, he complains of my want of fairness in not acknowledging the adequacy of the "evolutionistic agents" which he has suggested as "the causes of variation." With this specimen of Mr. Dixon's method of discussion before them, your readers may be able to sympathise with the failure which seems to have attended my efforts at expounding his essay.

The analogy between isolation and natural selection does not hold. For is it not obvious that while natural selection can be understood to operate in an explicable manner on the variations supplied to it, there is no analogous explanation to be given of the manner in which isolation can so operate—*i.e.* why isolation *per se* should preserve some of the variations and not others? That isolation is a favourable *condition* to the occurrence of trivial or non-adaptive specific change, I have not denied; but, on the contrary, expressly affirmed: I have only denied that it can be regarded as the *cause* of such change—and least of all in any way similar to that in which natural selection may be regarded as the cause of important or adaptive specific change. Therefore, if it is the case that "so many naturalists accept the theory of natural selection as an exclusive explanation of the evolution of existing species," I think that Mr. Dixon has done well to correct their error. Only I am not aware that any naturalist of note has allowed his belief in Darwinism thus to go beyond the teaching of Darwin.

GEORGE J. ROMANES

Scandinavian Ice-Flows

FAILING any more direct answer to Sir J. D. Hooker's query (NATURE, vol. xxxiii. p. 79), perhaps, with your usual courtesy, you will allow me space for one or two brief notes. The map referred to, as it stands in "Climate and Time," p. 449, is conjectural to a very large extent. If we are to take the relative closeness of the lines to indicate comparative depth and strength of the glacier-flow, the Baltic must have been, at the intensest period of glaciation, a glacier-filled valley, on an enormous scale, with the ice-stream passing out over the comparatively low, and then submerged, country of Schleswig-Holstein. Dr. Croll, to support a foregone conclusion, represents it thus, and then makes it bifurcate conjecturally about the Dogger Bank. One or two considerations, however, make Dr. Croll's conclusion less "inevitable" than he seems to imagine (p. 449).

(1) Admitting, as we must, that the striations mentioned (p. 448) on the Island of Bornholm, point to the passage of ice in massive proportions over at least that island in the *direction* indicated by the lines on the map, we may still call in question the hypothesis which regards the *main mass of the Baltic ice* as having passed that way.

For (2) the evidence given (p. 449) of its having passed over Denmark (the bare "fact that the surface of the country is strewn with debris derived from the Scandinavian peninsula") is so ambiguous as to be worthless on the point under consideration.

(3) The *facts* stated by Dr. Croll (stripped of the guise with which he has invested them) can be easily and naturally accounted for by the action of *marine* ice, owing its origin to the great Scandinavian glaciers of the period; some of which, even from the Baltic side, probably drifted away into the present North Sea basin.

But (4) that *the main mass* of the ice from the *eastern* slopes of the great glaciated Scandinavian range did not take this direction is proved by some of the best-established facts of European geology; facts which, had they been known to Dr. Croll, would have rendered, I venture to think, the construction by him of the map referred to impossible. On p. 447 he says, "After passing down the Baltic, a portion of the ice would probably move south into the flat plains in the north of Germany, but the *greater portion* would keep in the bed of the Baltic, and of course (*sic*) turn to the right round the south end of Gothland, and then cross over Denmark into the North Sea."

The *naïveté* of this statement, in a book bearing date 1875, is truly refreshing. Any one who knows the district of Jena is perfectly familiar with the enormous abundance of ice-transported material from Scandinavia to be found thereabouts; and these "Findlinge" are spread far and wide over the whole North-German plain as far inland as Bonn, Westphalia, Thüringen, Saxony (even to the south of Zwickau), and, according to Credner's later observations (*Sitzber. der naturforsch. Gesellschaft*, Leipzig, 1875), into the interior of Bohemia, as far as Troppau, near the sources of the Oder, on the slopes of the Sudeten Gebirge, and even to Toula and Moscow.

(5) Lastly, the occurrence of striated blocks of Scandinavian origin in the boulder-clays of the Yorkshire coast, is clearly incompatible with the conjectural view so graphically expressed on the map in question. A. IRVING

Wellington College, November 30

The Resting Position of the Oyster

I FEEL some disinclination to take up more space in the pages of NATURE on this subject without making any new contribution to the discussion, but Mr. John A. Ryder's letter induces me to summarise the facts which have been brought forward, and the conclusions to be drawn from them. The condition of the oysters examined by me can only be explained by inferring that they were quite free, and resting on a flat bottom with the right valve downwards. The specimens of *Pecten opercularis* which I had before me were in the same condition, and doubtless rested in the same position. Of *Pecten maximus* I cannot speak with certainty, and therefore leave to Mr. Arthur Hunt the responsibility of stating that there is a difference in respect of position in the two species. Prof. Möbius also finds that the left valves of oysters are usually covered by fixed animals, but as far as I understand his letter he thinks this does not prove that the left valves in this condition were uppermost: in the oysters I examined, the right valves were so clean that they must have been in close contact with the bottom. The other letters on the subject all describe evidence proving that oyster larvæ attach themselves by the left valve. This I did not deny, and I might of course easily have found the direct testimony of observers on the subject. Mr. Ryder says it is well known that the right valve of the oyster is always the most deeply pigmented, while the left one is paler; in the oysters I examined, the condition of the valves was exactly the reverse of this. It seems to me that when a young oyster is attached to the under-surface of a stone or shell by its left valve its right valve is lower, and if it drops from its attachment, or grows much larger than the stone or shell to which it is fixed, the surface of its right valve will come into close contact with the sea-bottom. I have seen oysters which still retained a piece of shell attached near the umbo of the left valve, while the rest of the valve was covered with fixed animals, and the right valve was quite clean and light in colour. There are no crowded oyster-banks in the Firth of Forth, and it might even be said that the oysters which came under my observation had been dredged and thrown overboard again at some time of their lives. But I do not think oysters are often returned to the water when once taken in the Firth. In my former letter I implied that probably in the normal position of an adult oyster the right valve was in contact with the bottom. That this is often the case when the oyster is free and has plenty of room has not yet been disproved, and therefore I think the current statement that the oyster, when not attached, invariably rests with its left valve downwards needs modification. J. T. CUNNINGHAM

Scottish Marine Station, November 28

The Sea-Mills at Argostoli

I WILL be glad if, through the columns of your journal, you will be good enough to inform me what has been written in English concerning the phenomenon known as "The Sea-Mills at Argostoli." Having recently visited the island of Cephalonia I was able to examine these mills frequently, and I have reasons for believing that papers have been read at different times at some of the learned societies at home discussing the subject *in extenso*. I will therefore be glad of *any* intelligence on this interesting phenomenon which you may be able to refer me to. J. LLOYD THOMAS

H.M.S. *Téméraire*, Mediterranean, November 15

Earthquake

ON Thursday morning, December 3, I was in bed awake, between 6 and 7 o'clock. I heard a slight clattering noise of the earthenware and glass articles on the marble top of the washstand. It lasted for about three seconds, and went .... with a slight halt near the end. There was no one moving in the house, and nothing outside to cause the tremors, which I did not feel in bed. I immediately got up to look at the clock, and found it was 6.45. I do not know at what time the earthquake in Algeria took place, possibly there was some connection between the two, and the tremor may have been felt in other places in England, so I record this.

Gateshead, December 6 R. S. NEWALL

VENTILATION

IN modern life, with its enormous populations living under artificial conditions in towns and cities, the subject of ventilation, or the supply of sufficient pure air to each individual for the maintenance of health, has assumed, as it has become more generally understood, a vast and national importance. Its importance has been clearly demonstrated in many instances by a greatly diminished death-rate in places where overcrowding on space or in houses, formerly existent, has been remedied, and especially by a decrease in those diseases which are now generally recognised as preventible. Thus, since attention has been paid to the amount of cubic space and the supply of fresh air per head in barracks, the death-rate from phthisis or destructive diseases of the lungs in the army has fallen from 10 to 2 per 1000; and typhus, formerly very prevalent in the gaols of the country and in the crowded courts of our large cities, is now almost unknown in these situations. That there is still a vast amount of disease and death which could be prevented by a more general recognition of the absolute importance of a pure supply of fresh air under all conditions, is a fact whose truth we recognise when we observe the numbers of scrofulous and ricketty children and consumptive adults in our large centres of population. Many houses in the poorer parts of towns are absolutely debarred from obtaining fresh air and light by their surroundings. Built almost back to back, or fronting into narrow courts or passages closed at one or both ends, the sunlight never penetrates for months in the year, and a free current of air is an impossibility. Fortunately the Legislature has recognised this evil, and the Acts known as Sir Richard Cross's and Torrens's are intended to remedy such a state of things, and, where enforced, have succeeded in removing buildings which no structural alterations could improve. The erection of huge blocks of Industrial Dwellings, whilst affording vastly superior accommodation to the working classes, has not always secured efficient ventilation in these respects for certain of the tenements. We have seen instances of lofty blocks being built in such a way as to enclose a narrow and well-like court, in which the atmosphere is always stagnant, and from which the inner rooms derive all their light and air. Cottage buildings, with sufficient space in front and rear, are far preferable to lofty blocks placed in rows; but as they do not house the same number of people for the space occupied in crowded districts, where land is of such enormous value, the rents must necessarily be higher, the other accommodation being the same. The air of enclosed courts is often damp, and being stagnant allows suspended particles to fall and foul gases to accumulate in it, thus forming a suitable "nidus" for the growth and cultivation of such disease germs as are capable of existing in the air. It is true that the death-rates appearing in the reports of many of the Industrial Dwellings Companies' are exceptionally low, but we must remember that a very large proportion of the working clases die in hospitals and not in their own houses, and such sources of error require to be very carefully eliminated. Of late years Artizans' Dwellings have been built on better principles, the experience derived from the sanitary failures of certain of the earlier erections having been taken to heart.

In the model bye-laws of the Local Government Board it is provided that no new street is to be less than 36 feet in width, that the frontage of any new building not standing in a street shall be at least 24 feet in width, and that there shall be an open space at the rear of any new building and belonging to it of an aggregate extent of 150 square feet, this space not to be in any case less than 10 feet wide, and if the height of the building exceed 35 feet, to be not less than 25 feet wide. If these rules could be always enforced in the cases of new buildings an improvement would be gradually effected in and around towns in the poorer districts which is greatly needed.

From what has been said it will be seen that one of the principal points in any system of ventilation is that the air to be admitted into a building should be pure, and this can be ensured if there is no impediment to the free circulation of currents of air on the outside. We come now to the second part of the subject, viz. the vitiation of air that is constantly going on in inhabited places from the respiration of men and animals, and from the combustion of gas, lamps, and candles, and the methods by which this vitiated air may be replaced by pure external air. The composition of the atmosphere is as follows in 1000 parts: nitrogen, 790·0; oxygen, 209·6; carbonic acid gas, ·4, and traces of ozone, ammonia with nitrous and sulphurous acids in the air of towns, and a variable amount of aqueous vapour. The air taken into the lungs of a human being has this composition, but that expired differs from it in the following particulars, the nitrogen remaining the same: the oxygen which is the vital principle of air is diminished 4 per cent., the carbonic acid is increased 4 per cent., the expired air is saturated with aqueous vapour and is heated nearly to the temperature of the body, 98° Fahr., and contains a small proportion of foul, decomposing organic matter, which exists partly in the form of vapour and partly as solid suspended matter (epithelial dust and scales). This organic matter, though small in amount, is the most injurious quality of expired air, giving to the atmosphere of an ill-ventilated room its close and disagreeable smell. Those who are familiar with the interiors of courts of law, with the pits and galleries of theatres, or with crowded buildings generally, are also familiar with the headaches, the lassitude, and the "malaise" produced by breathing for some hours a vitiated atmosphere. In analyses of such air nearly ten times more carbonic acid has been found than is normally present in the outer air, and when this excess is known to mean a deficiency in oxygen and a corresponding excess in organic vaporous exhalations and suspended matter from the breath and bodies of the persons present, the foul nature of the atmosphere can be realised. The slow deterioration in health, which results from the constant breathing of foul air, is one of its most important results, and causes a predisposition to, and lessened power of, resistance to attacks of disease.

An adult man of average size takes in and breathes out, when at rest, about 30 cubic inches of air at each respiration, this act being performed about seventeen times in a minute, so that in one hour about 17 cubic feet of fresh air will have been vitiated to the extent of containing 4 per cent. of carbonic acid—that is to say, about ·7 cubic foot. Such a man gives out when at rest, therefore, nearly ·7 cubic foot carbonic acid gas per hour. Now it has been found by Dr. De Chaumont, by chemical examination of a large number of samples of the air of inhabited rooms, that the amount of carbonic acid in the outer air being ·4 per 1000, no close smell is perceived in the air of a room until the carbonic acid reaches ·6 per 1000, or exceeds by ·2 per 1000 that in the outer air, the close smell being always due to the foul organic matter in the impure air, which increases *pari passu* with, and is therefore estimated by the amount of carbonic acid present. It has been assumed by De Chaumont, and experience has fully confirmed this assumption, that we can breathe with immunity air vitiated to this slight extent, but that we should not allow any greater vitiation. We may take it, therefore, that the object of ventilation is to supply sufficient pure air to a room to prevent the carbonic acid rising above ·6 per 1000, this quantity being known as the limit of respiratory impurity. It may be asked why should not the air of our rooms be as pure as the air outside? No doubt this would be desirable, were it not that it involves a continual renewal of the inner air by the outer, which means in cold weather an unceasing draught at an unbearable temperature. We have seen that an ordinary adult man expires ·7 cubic foot of carbonic acid in one hour when at rest, now if such an individual were enclosed in an airtight chamber, 10 feet high, 10 feet wide, and 10 feet long—that is to say, in a chamber containing 1000 cubic feet space—in one hour the carbonic acid in this chamber would have had added to it ·7 cubic foot of carbonic acid; the air originally contained ·4 parts of carbonic acid in 1000 parts, so that after one hour it would contain ·4 + ·7 = 1·1 parts of carbonic acid per 1000, or 1·1 − ·6 = ·5 parts per 1000 above the permissible limit for health. But if the subject of our experiment were enclosed in a room containing 3500 cubic feet of space, in one hour the amount of carbonic acid would be only $\frac{3·5 \times ·4 + ·7}{3·5} = ·6$ per 1000, *i.e.* the limit would have just been reached, and at the end of a second hour, to keep the carbonic acid to this limit, another 3,500 cubic feet of fresh air must have been allowed to enter the room. That is to say, an adult man requires when at rest 3500 cubic feet of fresh air per hour; a woman or child requires proportionally less. For any individual above twelve years of age, we may take as an average the amount of carbonic acid expired per hour as ·6 cubic foot, and for such an average individual 3000 cubic feet of fresh air per hour is necessary. We can now appreciate the importance of cubic space, for if we are to supply 3000 cubic feet of fresh air to every individual above twelve years in a room, and the amount of space, suppose, in a dormitory where ten persons sleep is only 300 cubic feet per head, then 30,000 cubic feet of fresh air must be supplied per hour—that is to say, the air of the dormitory must be completely changed ten times in this period, a proceeding which would cause in any but the very warmest weather a very disagreeable draught. But if the cubic space per head be 1000 feet, then the air of the dormitory need be changed only three times per hour, and if such renewal be effected steadily and gradually no draught need be felt. We may mention here that a certain amount of superficial or floor space is necessary for each individual, for if the height of the room is much over 12 feet, excess in this direction does not compensate for deficiency in the other dimensions, although the cubic space may be the same; thus it would not be the same thing to allow a man 50 square feet of floor space in a room 20 feet high, as to allow him 100 square feet of floor space in a room 10 feet high, although the amount of space allotted to him in each case would be the same. It may be interesting here to mention that in common lodging houses under police regulations, 240 cubic feet of space are allotted to each adult, in barracks about 600 cubic feet, in general hospitals about 1000 cubic feet as a rule, and in infectious fever hospitals from 1500 to 3500 cubic feet—in these latter institutions the floor space allowed per bed is from 150 to 300 square feet. From the report of the royal commission on the housing of the working classes it would appear that even the low allowance of the common lodging houses is very often not attained in the crowded rooms of tenement houses, and an enormous number of cellars are still inhabited in our large towns, although they presumably come up to the requirements of the Public Health Acts as regards their ventilation.

Gas, candles, and lamps use up oxygen and produce carbonic acid and water. A cubic foot of coal gas produces, when burnt, 2 cubic feet of carbonic acid, and since a common burner consumes 3 cubic feet of gas in an hour, it produces 6 cubic feet of carbonic acid in the same period. Therefore, as much air should be supplied to dilute the products of its combustion as would be necessary for three or four men. It is far better, however, to use such gas-lamps as are shut off from the air of the room. These receive the air necessary for combustion from without, and the products of combustion are carried off by a special channel to the outer air. The electric light uses none of the oxygen of the air and gives off no carbonic acid nor water, and is for these reasons far preferable to naked flames for lighting purposes.

Ventilation is said to be carried on by natural or by artificial means. In the former are included (1) diffusion of gases; (2) action of the wind by perflation and aspiration; (3) movements caused by differences in weight of masses of air at different temperatures. By the latter, although the same principles are involved, is meant exhaustion of air by heat or by steam from apartments, or propulsion of air into such spaces by mechanical means, as fans. Diffusion causes a rapid mixing of different gases placed in contiguity; thus the gaseous impurities of respired air mix with the fresh air in a room until homogeneity is established. Diffusion, however, does not affect the suspended matters which tend to fall in a still atmosphere. Consequently organic matters which exist principally as minute solids in a state of suspension in the air, are not affected or removed by diffusion. The wind when in motion causes a partial vacuum in the interior of tubes, such as chimneys and ventilating shafts placed at right angles to its course. The air in these tubes being thus partially aspirated or sucked out by the action of the wind, to restore the temporary vacuum so made, air from below rushes up to take its place, a continual current in a perpendicular direction being thus set up. Perflation by winds is the setting in motion of masses of air by the impact of other masses. This action is illustrated when the windows on opposite sides of the room are fully open. The room is rapidly and continually flushed with air, an enormous effect being produced, for it has been estimated that the air of such a room may be renewed many hundred times an hour, even when the movement of air outside is only 2 miles an hour or 1½ feet per second, equivalent to a very gentle and almost imperceptible breeze. Such a method is of unquestionable utility for rapidly changing the air of an unoccupied room, and may be generally put in operation in summer in inhabited rooms when the temperatures outside and inside the house approximate. In any system of ventilation that depends entirely on the wind there is always the difficulty of regulating the velocity of the current according to the amount of movement of the air, and during complete calms the action is nil. For ventilating the holds and interiors of ships at sea, the wind may be most advantageously utilised. A cowl placed so as to face to the wind conducts the air below, whilst another reversed so as to back to the wind allows the used air to escape.

The movement due to masses of air at different temperatures is the natural force chiefly relied on for ventilating the interior of houses. The air of inhabited rooms in this climate, except in warm summer weather, is at a higher temperature than the outer air; hot air is lighter than cold air, and will rise for cold air to take its place—in fact, heated air is displaced upwards by colder and denser air. In a room as usually constructed with sash windows, with a fire-place and chimney, but without any special means of ventilation, when a fire is burning in the grate the heated air of the room in part ascends the chimney-flue, and in part rises to the ceiling. Cold air from outside will then enter, if the windows be closed, under the door, under the skirting boards, between the sashes of the window, and through any other chinks or apertures due to loose fittings. The bricks and plaster of the walls are also porous to a slight extent, and if not covered with paint or wall paper will admit air to a limited extent. Thus a large volume of air may be entering a room in cold weather when the fire is burning although there be no visible inlets, and the amount of air thus supplied may be sufficient for the needs of two or three persons if it were properly distributed. But such is not the case. The cold air, which enters chiefly near the floor, takes as straight a course as possible to the fire-place, producing a disagreeable draught to the feet of the occupants, whilst the heated and vitiated air near the ceiling is left undisturbed. It has been found practically that to prevent draughts, and to ensure a thorough distribution, fresh air should be admitted into a room above the heads of the occupants, an upward direction being given to it, so that it may impinge on the ceiling, mix with, and be warmed by, the heated air in this situation, fall gently into all parts of the room, and be gradually removed by means of the chimney-flue or any other outlet. The inlet openings for fresh air now most in use are intended to serve this purpose. For sash windows Hinckes Bird's method, now so well known, of placing a solid block of wood under the lower sash of the window so as to raise the top of the lower sash above the bottom of the upper, admits the air in an upward direction to the ceiling above the heads of the occupants. Holes bored in a perpendicular direction in the bottom of the upper sash, louvered panes to replace one of the squares of glass, an arrangement for allowing one of the squares of glass to fall inwards upon its lower border and providing it with side cheeks, or a double pane of glass in one square open at the bottom outside and at the top inside—all effect the same purpose and are simple and inexpensive contrivances. Wall inlet ventilators, as the Sherringham valve and Tobin's tubes, are constructed on the same principles, fresh air, which in towns may be filtered through muslin or cotton wool, or made to impinge upon a tray containing water so as to deposit its sooty particles, being admitted at a height of about 6 feet from the floor and directed upwards towards the ceiling. The usual outlet for vitiated air is the chimney-flue, and this for an ordinary medium-sized sitting-room, with a fire burning, is sufficient for three or four people, provided no gas is alight, or the gas lamp has its own special ventilating arrangements. With an ordinary fire, from 10,000 to 15,000 cubic feet of air are drawn up the chimney in an hour. Valves placed so as to open into the flue near the ceiling are sometimes used as outlets for foul air, such are Neil Arnott's and Boyle's valves, which permit air to pass into the flue, but prevent its return; the only objections to their use are that they occasionally permit the reflux of smoke into the room, and their movements backwards and forwards cause a slight clicking noise. In all new buildings where efficient ventilation is desired, it would be preferable to construct a shaft at one side of, or surrounding the chimney-flue, with an inlet near the ceiling of the room and the outlet at the level of the chimney top, so that the air escaping from the room would have its temperature kept up by contact with the chimney, thus aiding the updraught, whilst the risk of reflux of smoke would be avoided. In all new domestic buildings a very great improvement might be effected by providing for the warming of the air before its entry into the apartments. The window and wall inlet ventilators just described are occasionally productive of draughts in cold weather, so that it is more usual to find them closed or stopped up than in action, or else admitting a very insufficient supply of air; but if the air be warmed before admittance to an agreeable temperature a very large amount may be allowed to enter without the fact being known to the occupants. The ventilating stove invented by Captain Galton, the Manchester school grate, and other forms effect this purpose in the following manner: Behind the grate, which is lined with fire-clay, is a chamber into which fresh air is admitted by a pipe from the outside. The air, here warmed, is admitted into the room by a pipe opening at about the level of the chimney breast and guarded by a grating which can be opened or closed as found convenient. In the Manchester school grate the warmed air is admitted by vertical pipes, like Tobin's tubes, opening on a level with the chimney-piece. The danger in these grates is that cracks may be formed by the heat of the fire in the joints or in the cast-iron plates which surround the air chamber, and thus direct communication be established between the grate and air chamber with the result of deleterious products of combustion being admitted into the air of the room. When the stove is lined with fire-clay there is no danger of the air in the chamber being overheated, producing charring of the organic matter in the air and an offensive smell, which is so often noticed around stoves where this precaution has not been taken. In Mr. Saxon Snell's ventilating thermhydric stove the fresh air is warmed by passing over hot water pipes in the stove before entrance into the room, the hot water being derived from a small boiler at the back of the grate. The temperature of the water is not high enough to overheat the air.

Gas is being gradually introduced for heating purposes, and with a reduction in its price we may look forward to its more extended use. There are several ventilating gas stoves by which air is admitted into a room warmed after passing through the stove. It is important to regulate the heat carefully so as not to overheat the stove and the air which is passing through. In churches and other public buildings air is usually warmed before entry by passing over hot water pipes which circulate around the building under the floor. In all large buildings the combustion of gas may be made a very effective means of getting rid of foul air. It has been found by experiment that the combustion of one cubic foot of coal gas causes the discharge of 1000 cubic feet of air. In theatres where gas, although being gradually replaced by the electric light, is still much used, the extraction of foul air from the roof of the building by the sunlight burners presents no difficulty. The difficulty experienced is the introduction of fresh air from below without causing draughts. In private houses the use of an extraction shaft over the gas chandelier or a Benham's ventilating globe light, or a Mackinnel's ventilator greatly aid the extraction of foul air from the ceiling, whilst the two latter are also useful in providing inlets for fresh air which enters slightly warmed near the ceiling, and is then directed horizontally by flanges so as to be distributed over the room. Outlets in the ceiling of a room may become inlets when a strong fire is burning, as the draught up the chimney will overbalance the extractive power of the gas and cause all other openings into the room to be inlets. We may here mention an ingenious method for warming the air admitted by Tobin's tubes into a room: a row of small Bunsen burners encircles the tube at its foot, and the products of combustion are conveyed away by a tube which surrounds the Tobin and opens into the outer air.

In large public buildings, where expense is no object, a combined method of ventilation by propulsion and extraction presents many advantages. The amount of air admitted can be easily regulated, warmed, cooled, or moistened, and freed from impurities by filtration, and enormous volumes are capable of being so supplied by propulsion and removed by the extractive powers of a furnace. In the Houses of Parliament where this system is in operation, air is propelled by rotatory fans along conduits to the basement, where it is warmed in winter by passing over steam pipes, and then passes upwards through shafts into the space beneath the grated floor of the House. The heat can be regulated by covering the steam pipes with woollen cloths, and in summer the entering air can be sprayed with water or cooled by passing over ice in the conduits. The vitiated air in the House passes through a perforated glass ceiling in the roof, and is then conducted by a shaft to the basement of the Clock Tower, where it passes into the flue of a large furnace.

The introduction of electricity for lighting and of gas for heating purposes will, in the case of both public and private buildings, considerably modify the methods of ventilation now most generally used.

CYCLES

THE Institute of Mechanical Engineers held a general meeting in the Corn Exchange, Coventry, on the afternoon of Wednesday, October 28, Mr. Jeremiah Head, President, in the chair, when the Secretary read a paper by Mr. R. E. Phillips, of London, "On the Construction of Modern Cycles," of which an abstract follows:—

The cycle industry in this country has grown with such rapidity and has already assumed proportions of such magnitude as to lead the author to hope that the present paper may prove of some interest to the Institution. It would not be possible within any reasonable limits to do justice to all matters connected with cycles; and he therefore purposes dealing only with their general construction, pointing out the underlying principles, and describing the various types at present made in order to show how far these principles have been carried out, and what degree of perfection has already been attained.

Power.—The experiments of Messrs. S. J. and G. S. Stoney show that with a lever action bicycle the power necessary to produce speeds of from six to fourteen miles an hour on an average road ranges from one-seventh to one-third of a horse-power; but the author thinks that less than this would be necessary with an ordinary rotary action bicycle.

Bicycle.—Gavin Dalzell, a cooper of Lesmahagow, in Lanarkshire, in 1836 first fixed a pair of cranks to one of the wheels of a hobby horse, and may therefore be considered the inventor of the bicycle. In 1868, Mr. Cowper, a past President of the Institution, specified, amongst other things, suspension wheels with wire spokes, hollow felloes, rubber tyres, and anti-friction roller bearings, and may thus be considered the inventor of the suspension wheel. Without these features or some modifications of them no cycle at the present day is satisfactory.

Tricycle.—Although the tricycle was invented contemporaneously with the bicycle it did not attract much attention until six years later.

Statistics.—Over one thousand patents were applied for for improvements relating to velocipedes before the end of 1883, and during 1884 (under the new Act) 637 applications were filed. There are 170 firms who devote themselves exclusively to cycle making, and turn out over 500 different machines. The trade employs 3000 men in Coventry and at least 5000 in the United Kingdom. About 40,000 machines are sold annually, of the gross value of about 800,000*l.*

Performances.—The following "records" are given:—

On a Racing Path

Distance run, miles	Duration of race, hours: Bicycle	Duration of race, hours: Tricycle	Mean speed, miles per hour: Bicycle	Mean speed, miles per hour: Tricycle
1	0·044	0·050	22·6	20·0
5	0·238	0·272	21·0	18·4
10	0·489	0·543	20·5	18·4
20	0·985	1·145	20·3	17·5
25	1·278	1·442	19·6	17·3
50	2·733	3·054	18·3	16·4
100	5·835	6·726	17·1	14·9

On Ordinary Roads

Journey	Bicycle: Hours	Bicycle: Days	Tricycle: Hours	Tricycle: Days
Distance of 100 miles	7·19	—	7·58	—
Land's End to John O'Groat's (about 900 miles)	160·17	= 6·67	197·33	= 8·22
Land's End to John O'Groat's and back, and thence to London, about 2050 miles	456	= 19		
Greatest distance in 24 hours	266¼ miles		231½ miles	
Mean speed for the 24 hours, miles per hour	11·1 ,,		9·6 ,,	

From these performances it appears that the bicycle has an advantage of from 2 to 2½ miles per hour.

Classification—

Bicycles

1. Bicycles of the ordinary type.
2. Safety Bicycles, which may be subdivided into—
   a. Dwarf bicycles with geared rotary action.
   b. Dwarf bicycles with lever action.
   c. Safety bicycles with steering-wheel in front.
3. Tandem bicycles.
4. Otto bicycle.

Tricycles

1. Single drivers, which may be subdivided into—
   a. Rear steerers.
   b. Coventry rotary, side steerer.
   c. Double front steerers.
2. Double drivers, which may be subdivided into—
   a. Those driving by clutch action.
   b. Those driving by differential gear.
3. Humber tricycles.
4. Hand power tricycles.
5. Sociables.
6. Tandems.
7. Carriers.

All these may be again subdivided as driven by "rotary" or "lever" action.

BICYCLES

Ordinary Bicycles.—The ordinary type of bicycle is so familiar that it need not be referred to at any length, especially as the details of construction will be dealt with later on. Being supported on only two points it is unstable, so it tends to fall one way or the other. Equilibrium is maintained by steering to that side to which it tends to fall. As the rider is seated only a little behind the centre of the driving wheel he is able by his feet alone to control the steering and so maintain his balance. When working the rider must counteract the thrust of his feet by pulling at the handle bar with his arms alternately on either side. It is this combined action which renders the riding of a bicycle so difficult to learn. The bicycle cannot be driven along a perfectly straight line, hence anything that interferes with the freedom of steering, as the groove of a tram line, makes the balance impossible.

Weight.—The weight of an ordinary roadster bicycle varies from as many pounds as its driving wheel is inches in diameter down to from 15 to 20 lbs. less than this. A racing bicycle weighs from 18 to 25 lbs., according to size. The proportionate weights of the several parts were given.

Vibration, which is the chief source of discomfort in most cycles, is mitigated by the use of india-rubber cushions between the wheel bearings and the forks, between the backbone and the spring, and between the head and the handle.

A spring fork was shown which serves to diminish the vibration produced by the small wheel of a machine.

Dwarf Bicycles with Geared Rotary Action.—Machines of this class have a smaller driving wheel connected with the pedals by chains and chain wheels. This makes it possible to "gear up" the driving wheel so as to be equivalent to one of any size. The high gearing thus introduced is the cause, in the author's opinion, of their ease of propulsion and speed.

Dwarf Bicycles with Lever Action.—The "Facile" bicycle is a prominent example of this type of machine. The motion of the feet is simply reciprocating, and as the wheel is not "geared up" the feet keep time with the driving wheel.

The 'Xtraordinary is another example of a lever action machine. In this machine the fork rakes back to a great extent so that the rider is far behind the centre of the driving wheel, but the pedal levers bring the pedals to a convenient position. Their path is oval. These machines are made of the full size.

Safety Bicycles with Steering Wheel in Front.—In machines of this class the rider sits well over the driving wheel, which is behind. A single chain is sufficient, as in this kind of machine there is a "through" crank-axle. In a modification of this pattern a divided crank-axle is employed, which allows the rider to be still more over the driving wheel. The frame, moreover, is made capable of swinging and of being locked in various positions, so that the rider can place himself in the best position under all conditions.

Machines of this type are rather sensitive in the steering, but as automatic contrivances to keep the steering wheel running straight are apt to interfere with that freedom which is necessary for the balance, such devices are not altogether desirable.

In these machines the feet cannot be used to control the steering as in an ordinary bicycle, but the author of the paper has contrived a means for effecting this. On the centre of the crank axle is a spherical boss, on which can swivel, but not turn freely in all directions, a large double hollow chain wheel kept parallel to the driving wheel by two idle rollers. As a matter of fact the crank axle swivels within this chain wheel and the brackets which support it being rigidly connected with the handle bar serve to steer the machine.

Tandem Bicycles.—At present there are only two makes of tandem bicycle, each invented by Mr. Rucker. The earlier one is constructed of two ordinary bicycle driving wheels complete in their forks, which are then connected by a backbone containing an axial joint. Each rider drives, steers, and balances on his own wheel independently of the other, but of course the rear must follow within a foot or so the path of the one in front. Although this machine is very fast, lighter than two ordinary bicycles, and almost entirely free from vibrations, there is an element of danger about it that militates against its general use, inasmuch as it demands to a certain extent a unity of thought and action on the part of both riders.

A very satisfactory tandem has been arranged by the author, a modification of this, in which the rear wheel is replaced by the driving wheels of an ordinary Humber tricycle, the connecting bar of course being modified to suit the altered conditions. The later tandem bicycle eclipses the earlier; it is probably the fastest machine in existence. It is constructed on the lines of a dwarf geared bicycle. The seat for the front rider is mounted immediately over the centre of the driving wheel, while the rear rider who alone steers and manages the machine is about midway between the two wheels. Divided pedal axes are mounted fore and aft of the centre of the driving wheel. The weight of this bicycle is only 55 lbs.; it is therefore the lightest machine yet made to carry two riders.

Otto Bicycle.—This peculiar machine, which is due to the brother of the inventor of the gas engine known by the same name, is almost more nearly allied to a tricycle than to a bicycle proper, but as it has only two wheels and consequently requires the balance to be still maintained by the rider, it is rightly called a bicycle. The wheels are the same size, and are here mounted loose on the same axle, parallel to each other and both of them are drivers. The rider sits between them and works a continuous pedal crank-axle, the position of which when he is seated is below and slightly in front of the axle carrying the driving wheels. The crank axle is connected with the driving wheels by endless steel bands passing round plain pulleys on the ends of the crank-axle and on each wheel. The bands are kept taut by tightening springs, and the machine is steered by slacking one or other of them, which causes the corresponding driving wheel to lose motion, and therefore the other wheel runs round it. If a very sharp turn has to be made suddenly, a brake is applied to one wheel at the same time that its driving band is slackened, which causes the machine to turn round in a circle upon that wheel as a centre. This machine having no small wheel fore or aft, the rider, while steady sideways, has to balance himself in the direction of his motion, which he is enabled to do through the medium of the pedal crank axle; by pressing on the forward pedal, if he is falling forwards, he throws his weight backwards and conversely by pressing on the rear pedal he throws his weight forwards. To preserve him from actually capsizing backwards a safety tail projects behind the seat, which will bear on the ground whenever the seat is tipped too far back.

Among the many beautiful features presented by this machine the best seem to be: (1) the balance whereby the rider is always in the best position to utilise his strength and weight notwithstanding the various gradients; (2) the nicety by which it can be steered; (3) its tendency to run in a straight line without any effort on the part of the rider; (4) its freedom from vibration; (5) the circumstance that it makes only two tracks.

TRICYCLES

The tricycle presents far greater difficulties than the bicycle. It is necessary that each wheel shall be free to move in its own direction independently of the united action of the other two. For running in a straight line all three wheels must be parallel; whilst for running round a curve, one or more of the wheels must be turned until the centre lines of the axles intersect in plane, their point of intersection being the centre of the path described. Besides being independent in direction of running, each wheel must also be capable of revolving at a greater or less speed than the others. It is also essential that only so much of the rider's weight shall be borne by the steering wheel or wheels as is necessary to ensure their proper action. Owing to the variety of ways in which these principles can be carried out practically, it is easy to account for the variety of tricycles constructed.

Single-driving Tricycle.—The simplest form of tricycle is that with only one driving wheel, either or both of the others being used for steering. The single driving rear-steerer is now practically obsolete.

Coventry Rotary Tricycle.—Another single driver, known as the "Coventry rotary," has the large driving-wheel on one side, and two small steering wheels on the opposite side, arranged to turn together in contrary directions for steering. The double steering counteracts the evil of one-sided driving. Though one of the first machines introduced it is still largely in use, its advantages being that it is simple, it makes only two tracks, and it is narrow enough to pass through an ordinary doorway; this, however, diminishes its natural stability.

Front Steering Tricycle.—A single driving machine of this class exists which is steered by the two front wheels, and driven by the rear wheel, but there is not sufficient weight on the driving wheel.

Double-driving Tricycles.—In these the two driving wheels are always placed parallel and opposite to one another, with the steering wheel in front or behind, and generally central. It is sometimes placed on one side when the tricycle makes only two tracks. There are two methods of double-driving: firstly, by clutch-action; secondly, by differential or balance gear.

Double-driving by Clutch Action.—In this plan the two driving wheels are locked to their axle only when the machine is being driven forwards in a straight line, but in running round a curve the outer wheel overruns the clutch and the inner wheel alone drives. In the Bourdon Clutch, which is most generally used, a disk has its edge cut away so as to form three or more inclined planes. In each of the spaces between these recesses and an outer ring is a hard steel roller, which jams when the clutch drives the wheel, but which does not hinder the wheel from running ahead of the clutch.

A clutch machine cannot, without extra gearing, be driven backwards, nor can it be retarded except by the action of the brake. On the other hand the free pedal is a convenience. Various attempts have been made to construct a clutch which shall drive either way, but hitherto without success, in consequence of the loss of time between the forward and the backward grip. The author of the paper is now at work on this problem.

Double Driving by Differential or Balance-Gear.—This other mode of double driving, so called because the power is divided or balanced between the two driving wheels, depends on the action of an epicyclic train, in which the two primary wheels are connected with the driving wheels of the tricycle, while the arm or train which connects them is driven. The simplest form invented by Starley consists of three bevel wheels. Here the arm or axis of the middle one being carried round, drives the other two and hence the driving wheels, which nevertheless can move independently. Other gears were spoken of, and a figure of the Sparkbrook gear given.

Each kind of driving has its advantages. When running straight the clutch system drives each wheel, and when one wheel meets with more resistance than the other, as much extra force as is necessary is supplied to it, so that obstacles are surmounted with less chance of swerving. In going round a corner only the inner wheel is driven.

With balance-gear the same force is applied to each wheel, whether the path is straight or curved.

A rear steering tricycle driven by clutch action, a rear steerer driven by differential gear, and a front steerer driven by differential gear were exhibited.

Humber Tricycle.—Among tricycles driven by differential gear, the Humber is quite peculiar. The rider sits astride a back bone carrying a trailing wheel, and steers by turning the axle of the two driving wheels by means of a handle bar. The differential gear is essential to a machine of this type, as it does not interfere with the steering, while it is at all times perfectly double driving.

A curious machine—a modification of the Humber—was shown, in which all three wheels take part in the steering, but of entirely novel and elegant design.

As with bicycles, so with tricycles, the power may be applied in one of two ways: either by rotary action or by lever action. For changing the power, levers are more convenient, but they do not compare with rotary action in point of speed.

Omnicycle.—One of the most successful lever machines is the omnicycle, a machine in which the pedals are connected with the circumference of a segment by means of a leather strap. When one pedal descends it causes the segment on the other side to return and raise the pedal on that side. The segments can be expanded to various extents, so that the power is applied with various degrees of leverage according to the work to be done.

Direct-Action Tricycle.—The simplest rotary tricycle has no chain or connecting mechanism; the pedals are on the main axle, which is cranked. This gives rise to the insuperable objection of instability as the rider is necessarily perched up high. By the use of hanging pedals a few inches are gained.

Transmission of Driving-power.—Reverting to the ordinary type of tricycle in which the power is applied to a crank axle and transmitted thence to the main axle, there are three plans commonly in use—(1) by chains or bands: (2) by gear wheels; (3) by cranks and coupling-rods.

Driving-Chains. These are the most popular means of transmitting power, as they offer the greatest facilities for gearing up or down. The Morgan and the Abingdon chain were figured and described.

Driving-Bands.—Steel bands, plain or perforated, have been used with some success. The Otto bicycle is the only machine in which plain bands are used for driving. The power spent in continuous flexure of the bands outweighs, in the author's opinion, any other advantages they may possess.

Gear-Wheels.—In this system an intermediate wheel gears with those on each axle; but as the wear cannot be taken up without destroying the pitch, the plan is hardly satisfactory. Rollers are occasionally fitted over the teeth of the intermediate wheel.

Coupling-Rods.—Coupling-rods are used on a few machines; with the exception that they will not permit of gearing up or down and that they cannot be used with differential gear, they give very good results.

Another method due to Mr. Boys, in which eccentrics and steel bands are employed, was also referred to.

(*To be continued.*)

NOTES

Dr. Asa Gray was presented, on November 18, being the seventy-fifth anniversary of his birth, with a silver vase, by the botanists of America. It is described by *Science* as being about eleven inches high, and is appropriately decorated with those plants which are distinctively American, and which are most closely associated with Dr. Gray. The place of honour on one side is held by *Grayia polygaloides*, and on the other by *Shortia galacifolia*. Among others, *Aster Bigelovii, Solidago serotina, Lilium Grayi, Centaurea americana, Notholæna Grayi*, and *Rudbeckia speciosa*, are prominent. The workmanship is described as highly artistic, as well as remarkably accurate. The vase stands on a low ebony pedestal, which is surrounded by a silver hoop, bearing the inscription:—

1810—November Eighteenth—1885
ASA GRAY
In token of the universal esteem
of American botanists.

The greetings by card and letter of the one hundred and eighty contributors were presented on a plain but elegant silver tray. They contained the warmest expressions of esteem and gratitude.

As we intimated last week, the death took place in Paris, on the 30th ult., of M. Bouley, President of the Academy of Sciences, after a long and painful illness. Although, says the *Revue Scientifique*, he did little original work in science, he exercised a wide influence on its general progress as well as on scientific education. He did much to raise in public consideration the art and science of veterinary surgery and medicine. Latterly, he became the ardent apostle of the teachings and discoveries of M. Pasteur, and to this work he devoted his lucid and vigorous eloquence. His books on experimental disease and on contagion are models of scientific style, as his lectures at the Museum were models of instruction.

The death is announced, at the age of eighty years, of Prof. Giuseppe Ponzi, the Italian geologist.

The fifth edition of the "Admiralty Manual of Scientific Inquiry" is now being prepared for press, under the editorship of Prof. Robert S. Ball, F.R.S., Royal Astronomer of Ireland The following is a list of the articles, with the names of the authors or revisers:—Astronomy, by Sir G. B. Airy, K.C.B., F.R.S.; Hydrography, by Capt. W. J. L. Wharton, R.N., Hydrographer of the Admiralty; Tides, by Prof. G. H. Darwin, F.R.S.,; Terrestrial Magnetism, by Prof. G. F. Fitzgerald, F.R.S.; Meteorology, by Robert H. Scott, F.R.S.; Geography, by Sir J. H. Lefroy, F.R.S.; Statistics, by Prof. C. F. Bastable, M.A.; Medical Statistics, by W. Aitken, M.D.; Ethnology, by E. B. Tylor, F.R.S.; Geology, by Prof. Archibald Geikie, F.R.S.; Mineralogy, by Prof. W. J. Sollas, D.Sc.; Earthquakes, by Thomas Gray; Zoology, by Prof. H. N. Moseley, F.R.S.; Botany, by Sir J. D. Hooker, K.C.S.I., F.R.S.

Now that M. de Lacase-Duthiers has completed his arrangements for the marine laboratories at Banyuls and Roscoff, his friends and admirers have deemed the moment a suitable one for manifesting their sense of the value of his services to the study of zoology in France, and to zoologists all over the world, and it is hoped that all those who are connected, either by their studies or their sympathies, with the zoological school founded and directed by him, will join in the work. The proposal is to have his portrait etched by one of the best French artists, and to give a copy to each subscriber of ten francs or more. The number of copies will be strictly limited to the number of subscribers. The Universities or schools of Athens, Paris, Caen, Geneva, Liége, Cairo, Edinburgh, Clermont, Besançon, Lyons, and Poitiers are represented on the Committee. Subscriptions may be sent, before December 16, to M. J. Joyeux-Laffuie, of the Faculty of Sciences, Besançon, or, in this country, to Prof. Geddes, 81A, Princes Street, Edinburgh.

The new balloon constructed by the Meudon aëronauts, will be directed by a steam-engine, as advocated by M. Henry Giffard. Electricity will be quite given up, owing to its want of power for continuous action. From the reports to be published in the next number of the *Comptes rendus*, it appears that a velocity of six metres per second was obtained.

The Tokio Correspondent of the *Times* describes a strange linguistic revolution which is coming over Japan. Hitherto the Japanese language has been written by Chinese ideographs, or pictorial symbols, of which many thousands had to be learned by every youth. There were also two syllabaries or alphabets which were used by the common people, but no one could enter on the path of knowledge without first acquiring a knowledge of the Chinese characters, "a task which not only needed a very heavy expenditure of time, but was also calculated to stimulate the memory in an abnormal degree at the cost of other not less important mental faculties." Moreover, with the new science from the west before them, Japanese youth "could hardly afford to spend years and warp their brains in learning the single accomplishment of writing thoroughly their own tongue." A movement, which appears to be as national as such a movement could be, has now been set on foot to discard all existing methods of writing Japanese in favour of Roman letters. A society called the Roman Alphabet Association has been founded for the purpose of disseminating knowledge on this subject and of providing a uniform method of transliteration. It now consists of nearly 6000 of the leading men in the governing, educated, and literary classes. Stupendous as this change may seem to us, there is really no reason why it should not successfully be carried out. It meets in Japan a crying evil, which stunts the mental growth of its youth, places a barrier between them and the science and discoveries of the age, and which haunts and embarrasses them in their subsequent studies unless they acquire a foreign language at once in order to get rid of this incubus. Besides, the Japanese language is now written in borrowed symbols; Chinese characters are as alien to it as Roman letters; but the former have been in use a thousand years, and if the Japanese can now succeed in getting rid of them they will have accomplished a revolution more marvellous and not less beneficent than any they have passed through in the last seventeen years.

We have received from Mr. Twining a pamphlet, of which he is the author, on "Science for the Middle and Upper Classes," which is intended for the consideration of those interested in educational progress (London: J. J. Griffin and Sons, 22, Garrick Street). He first deals with the chief purposes of scientific instruction, which he classes under the heads "bionomic" ("bionomy" being his convenient expression for the science of daily life) "intellectual," "technical," and "professorial." He then draws up and discusses a scheme of scientific teaching extending over the whole school period of a boy. There are, in addition, numerous observations on the teaching f various branches of science. Mr. Twining's pamphlet is herefore essentially for the teacher, and, as he has evidently devoted great attention to the subject, and is himself engaged in the practical work of education, his pamphlet should prove useful and suggestive.

In the *Revue Scientifique* M. de Lacaze-Duthiers describes a curious phenomenon which he has observed in a parrot belonging to him. The bird is very intelligent, having an excellent memory for his friends and his enemies; of this trait and other marks of intelligence the writer gives several instances. The point of the article, however, is this:—The parrot has manifested an extraordinary affection for a little boy named Raymond, but usually called by the Southern diminutive, "Momon." The child called M. Duthiers's attention one day to the fact that, whenever he played with the bird, the eyes of the latter became quite red. When the boy went away, the parrot would call out his name perpetually; when he returned, it would walk to and fro on its perch, exhibiting every mark of extreme pleasure; and the eyes invariably grew red. At these times it would allow no one else, however friendly, to approach the cage; it would not eat its most favourite food. When the boy hid himself for a moment, the eyes became yellow, but suddenly reddened again when he reappeared. This phenomenon was observed only with this particular child, and with no one else. When the boy went to school, or when the bird was brought to Paris from the country, it ceased completely. An examination of the bird's eye showed that the pupil is large, and usually dilated. The iris is only represented by a circular yellow band, bordered externally by a bright red strip. The pupils of parrots are known to be very mobile. When the bird manifests joy, it contracts the iris *voluntarily*, the yellow disappears, and the red strip occupies its place, spreading itself out all over the surface of the back of the anterior chamber of the eye, giving the striking red tint observed first by the child. Here, then, is a bird, intelligent, and full of affection for a particular person, manifesting its joy by the contraction of its pupils, and thus voluntarily modifying the colour of its eyes. When violently angry, some streaks of red dart across the eye, but they never remain as in the other case. It is curious, concludes M. Duthiers, to see a phenomenon, regarded as independent of the will in the superior animals, thus found in association with feelings and acts which determine joy or anger, and which is apparently as voluntary as the movements of the feathers and all other essentially voluntary acts.

Herr Stejneger continues to supply *Naturen* with interesting reports of his recent boating expeditions in Behring's Sea. In the latest of these we find much valuable information in regard to important changes to which the fauna of these regions is being subjected through the reckless destruction of some animals, and the rapid spread of others by the introduction, through the agency of man, of previously unknown species. Thus, while there were upwards of 5000 sea-otters (*Latax lutris*) killed on the Prybilof Islands in the first year of their occupation, after six years not one of these animals was to be found on the spot, nor have they ever reappeared there during the century that has elapsed since then. At Mednij, on the other hand, where otter-hunting is conducted with moderation and under legal restrictions, there is no marked diminution in the numbers of these animals, and there is at present every prospect that the supply of skins will continue to yield a fair source of wealth to the inhabitants. The killing of foxes is similarly controlled in some districts, where the natives refuse to allow Master Reynard to be hunted, excepting in the last three months of every second year, during which time no one is allowed to fire a gun, or drive with dogs along the coast, lest the sound of the shots and the barking should interfere with the success of the licensed fox-hunters, who on these occasions occupy the earth huts specially set apart for their use in the several districts.

Owing to the moderation shown in its pursuit, the Behring Straits fox, known as the blue fox, from the colour of its skin in winter, seems for the present to be in no danger of dying out, several of these animals being generally visible on the strand of every little bay, where they arrest attention by their loud, howling bark, which is often continued hour after hour through the night. Till recently they might have been regarded as the only terrestrial quadrupeds on Behring's Island; but in the present day the brown field-mouse (*Arvicola rutila*), which was unknown eleven years ago, has made good its footing on the island, swarming over every district, from the heights of the fjelds to the flats of the tundra, and from the interior to the most exposed rocks along the coasts. Till 1874 the mouse family was unknown on the island, the oldest inhabitants never having seen one of the species prior to that date, when the gray mouse (*Mus musculus*) unexpectedly made its appearance, having probably been introduced in a cargo of flour from San Francisco. The advent of these pests was followed a few years later by that of the more destructive brown field-mouse, a phenomenon which the simple natives explain to their own satisfaction by assuming that the shorter-tailed rodent is a descendant of the long-tailed gray mouse, which had thus changed its colour and appearance the better to adapt itself to its novel terrestrial life. Mednij is still free from these undesirable immigrants, but the fact is not regarded in the light of a happy exemption by the inhabitants, who, considering this short-tailed little quadruped as specially adapted for a domestic pet, petitioned the authorities to provide them with an adequate supply. Their eager desire for the acquisition of rodents has, fortunately for them, been only so far complied with that, in place of the coveted voles, a few rabbits were sent to the island.

Naturen draws attention to the notices to be found among Scandinavian authorities of the observation in past times of the same after-glow in the sky which has in recent years been made the subject of so much discussion. Thus we learn from a Danish journal that the glow in the skies observed in 1636 by seamen navigating the northern seas was ascribed at the time to the eruption of Hecla which occurred in that year. From the same source we derive a circumstantial notice of a similar phenomenon observed in Copenhagen on May 29, 1783, which continued, with slight variations, till the close of the following September. In the months intervening between these dates the heavens were illumined by a constant red glow, although the sun appeared by day like a faint disk, and was wholly invisible at its rising and setting. The air is said to have remained unaffected by cold or heat, rain, or dry weather. The superstitious were not slow in interpreting these unwonted phenomena to portend great national troubles, while some persons even regarded them as the immediate forerunners of the end of the world. After a time, however, news reached Denmark that there had been an unusually violent eruption of the Skapta Jökul in the previous spring, and thenceforth a conjecture was advanced that the remarkable redness of the sky might, as in 1636, be connected with the great outbreak of volcanic energy in Iceland.

A NEW discovery of apatite is reported from Stavanger, where, about 30 kilometres east-south-east of the spot at which Herr Enoksen found this mineral last summer, its presence has again been detected in a granitic formation near Lerwik. Here it appears in a finely granulated form intermixed with nickel and magnetic iron pyrites, the masses varying in size from 18 to 38 inches in diameter, and lying detached in a dark deposit, which is believed to be mica diorite. In the matter of mineral finds of real value the Stavanger district has been specially favoured in recent times, and we are glad to learn that the sanguine expectations excited by the accidental discovery in 1881 of a zinc mine near the head of the Sövdefjord, have been fully justified by the result of the yields. On a more careful examination it has been ascertained that these mineral deposits extend horizontally for a distance of 80 metres, while they have been traced to a depth of 60 metres. The ore is blende, or sulphide of zinc, which appears in flat perpendicular masses, from 50 centimetres to 4 metres in thickness.

THE Russian Government has assigned the sum of 255,500 roubles to be expended during the year 1886 in new geodetical surveys in Ferghana, the territories bordering on China, the Usuri district, the Transcaspian province, and Finland.

THE Government of Tasmania are making arrangements upon a large scale for naturalising lobsters, crabs, turbot, brill, and other European fishes in the waters of that country. The various consignments will be shipped at Plymouth, and transported through the medium of the steamship companies trading between London and Hobart. An exhaustive report has been published by the Government of Tasmania, setting forth the objects in view, and giving suggestions for carrying them into effect. The report adds that while the achievement of the acclimatisation of European fishes would lay the foundation of new and very valuable fishing industries in Tasmania, it might also prove a highly remunerative commercial enterprise to the shipping firms under whose auspices the operations wil be conducted. Applications have been made in various quarterl for supplies of fish, which have been satisfactorily responded to. Special tanks are being prepared, as well as apparatus, in order to provide for the necessities of the fish *en route* which, it is anticipated, can be transmitted with little difficulty. The success that has hitherto attended the acclimatisation of certain European fishes in New Zealand has had the effect of inspiring the Government of that colony with considerable enterprise in developing their fisheries. They are now about to collect the ova of *Salmonidæ* from English waters in large numbers through the instrumentality of the National Fish-Culture Association, and other bodies, with a view to rearing the fry in New Zealand. A shipment of eggs will also shortly be sent to Australia, where great success has attended the introduction of our fishes, except in a few instances, when failure resulted more from misadventure than from the impracticability of the attempt.

A DREADFUL earthquake occurred in Algeria on the night of December 3–4. The centre of commotion seems to have been located near M'sila, a small town in the interior. The place was disturbed a second time on the following morning. The last commotion was more destructive than the first. The number of victims is estimated at one hundred. The commotion was felt at Setif and at Moscara, whose distance is about 400 kilometres. Their direction was east to west. The difference was 7 seconds at Setif, and 8½ at Moscara, where three different shocks were felt. The commotion was noted also in Algiers without any accident being recorded. According to latest news, the series of earthquakes is continuing with unabated energy. We learn that on the night of the 4th to the 5th inst. a port of Bousaada, a town of 6000 inhabitants, almost exclusively Arabs, has been partially destroyed. The church and seventy-one houses have been demolished; the victims are not numerous, all the population having encamped in the fields. This town is the centre of a large market, celebrated in all the south of the province of Algiers, 254 kilometres south of the city. Another telegram states that other commotions were felt on the 6th at M'sila for the second time. These last shocks are reported very heavy; time, 2 and 4 p.m. The time appears to have been the same at M'sila.

OUR Paris correspondent writes that in relation to the balloon which is said to have been seen over Bermuda in September, no ascent took place in France which can account for it.

WE learn with regret that M. de Mortillet, the sub-Director of the Prehistoric Museum at St. Germain, has been obliged to resign owing to his election to the French Lower House as a Member for Versailles. A competition has been opened to fill up the post vacated by his resignation. The Society of Anthropology and similar scientific institutions have signed a recommendation to the Minister of Public Instruction on behalf of M. Adrien de Mortillet, who has been associated with his father in the publication of his recent works on prehistoric science.

THE additions to the Zoological Society's Gardens during the past week include a Sly Silurus (*Silurus glanis*), European, a Thunder-fish (*Misgurnus fossilis*), a Ground Loach (*Cobitis tænia*) from Danzig; a Barbel (*Barbus vulgaris*), a River Bullhead (*Cottus gobio*) from British fresh waters, presented by Mr. Alban Doran, F.R.C.S.; one hundred Golden Carp (*Carassius auratus*) from Spain, presented by Messrs. Paul and Co.; a Black-shouldered Kite (*Elanus cæruleus*) from Africa, received in exchange.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *DECEMBER* 13-19

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 13

Sun rises, 8h. 0m.; souths, 11h. 54m. 33·8s.; sets, 15h. 49m.; decl. on meridian, 23° 12′ S.: Sidereal Time at Sunset, 21h. 19m.

Moon (at First Quarter on Dec. 14) rises, 11h. 48m.; souths, 17h. 16m.; sets, 22h. 53m.; decl. on meridian, 6° 51′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	8 53	12 48	16 43	23 8 S.
Venus	11 4	15 18	19 32	20 5 S.
Mars	23 0*	5 43	12 26	7 52 N.
Jupiter	0 45	6 47	12 49	0 23 S.
Saturn	16 49*	0 58	9 7	22 27 N.

* Indicates that the rising is that of the preceding day.

M signifies maximum; *m* minimum.

Meteor Showers

A shower from the constellation of the Quadrant, radiant, R.A. 220°, Decl. 53° N., may be looked for throughout the week, after the moon has set.

A small shower with radiant in the constellation of the Lynx, R.A. 108°, Decl. 63° N., has been observed by Schmidt and Zezioli during this week of the year.

Stars with Remarkable Spectra

V Cygni R.A. 20h. 37m. 36s., Decl. 47° 43′·8 N., variable. Secchi's fourth type. The blue end is either wanting or extremely faint. The two dark bands usually seen in the orange in stars of this type seem absent, but the dark band in the yellow is very pronounced.

	R.A. h. m. s.	Decl. ° ′		
Birmm. 566	20 32 50	17 52·0 N.	Mag. 7·0	Three well-marked examples of the third type
Birmm. 569	20 40 13	17 40·5 N.	Mag. 6·8	
L.L. 40182	20 43 24	0 59·2 S.	Mag. 6·8	
ρ Persei	2 57 48	38 23·8 N.	Variable	Three typical representatives of the third class
α Orionis	5 48 58	7 22·9 N.	Variable	
π Aurigæ	5 51 24	45 55·5 N.	Mag. 4·8	

α Orionis and ρ Persei show many fine metallic lines beside the system of dark bands, shading off towards the red, which forms the characteristic of the third type of stellar spectrum. These brighter stars should be by all means examined with the fainter stars of the same type that the observer may become perfectly familiar with the characters and positions of the principal bands.

The *Dun Echt Circular*, No. 101, issued on December 5, from Lord Crawford's Observatory, says that the announcement has been received by Harvard College Observatory, from Dr. Lewis Swift, Director of the Warner Observatory, of the discovery of a comet by Barnard.

EXPLOSIONS IN COAL MINES[1]

II.

THE superficial observer, in noting the real progress made during the last few years in the facility and success with which the electric light has been utilised in a remarkable variety of directions, might have been pardonably led to the conclusion that there existed no very great difficulties in the way of at once presenting the miner with an electric light in almost as portable a form as a safety lamp—incomparably safer than the best of these—and capable of affording a much superior light for the entire duration of his longest working hours underground. A little inquiry into the subject demonstrated to the Royal Commission that such a conclusion would be at least very premature, and that, although the subject was one most worthy of patient pursuit, the attainment of really useful results was beset with formidable difficulties. It is one thing to announce in oracular fashion, as the *Times* did, in a leading article last June, "that collieries ought to be lighted in a way to dispense with safety lamps," and "that electricity is the one illuminating medium which can supply the light which miners want, without the flame which endangers them." It is quite another thing to apply the electric light with safety, even along main roadways, in mines in which fire-damp is prevalent. The writer of those lines would have been less confident in his assertions had he sought sufficient information to teach him that the fracture of a glow-lamp, or the rupture of a conducting wire in a mine, might be as much fraught with danger as the injury of a safety lamp or the lighting of a pipe. Had he, moreover, but learned by simple inquiry what progress had been made by patient workers (at the time he was inspired thus to write), towards setting aside those sources of danger and providing the miner with a portable and efficient self-contained lamp, he would certainly have hesitated to assert that "no proper zeal has been brought to bear upon the conquest of difficulties" in the application of electric lighting in mines, or to sneer at "the scientific brains, whom the public may encourage, though it cannot compel, to exert themselves as keenly for the

[1] Address of Sir Frederick Abel, Chairman of Council of the Society of Arts, delivered at the opening meeting, Nov. 18, 1885.—(Abstract by the Author.) Continued from p. 112.

illumination of a murky, dirty coal-pit, as in the transformation of a plot of ground in South Kensington into fairyland."

Attempts have been made in several of the mining districts to apply electricity to underground illumination; so far as distribution of the light in main roads is concerned, no great progress has been made, though there is now no reason why glow-lamps, protected after the manner in use at our Government Gunpowder Works (as shown in the recent Exhibition), should not be distributed to considerable distances along such portions of a mine. At Risca Colliery, in Monmouthshire, at Harris's Navigation Colliery, near Pontypridd, and at Earnock Colliery, at Hamilton, N.B., a commencement has already been made in this direction with satisfactory results. If, however, the miner is to have an electric lamp for lighting up drifts and working places, it must be supplied to him in a self-contained and really portable form, with absolute isolation of the glow-lamp from the surrounding atmosphere, and with a store of power sufficient to maintain an efficient light for ten or twelve hours.

The considerable improvements which have of late been effected in accumulators, and the advance which has also been made in the construction of constant primary batteries, have led to very important progress toward the attainment of these essentials. Mr. J. Wilson Swan, universally celebrated for his achievements in the matter of glow-lamps, has patiently pursued the subject, and has not long since succeeded in producing a lamp which, with its small storage battery, weighs little more than 8 lb., and which will furnish a light equal to from two to four times that given by the better forms of safety lamp for a duration of ten or twelve hours. Mr. Swan is sanguine that he will ere long be able to effect an important reduction in the weight and bulk of the lamp, and he is not less hopeful of elaborating a primary battery similar in portability and light-giving power, the substitution of which, if successful, for the accumulator would have the advantage of dispensing with the necessity for providing dynamo-electric machines and power for charging the storage cells. Other workers besides Mr. Swan, such as Mr. Coad and M. Trouvé, have been applying small primary batteries to the production of miners' lamps with some promise of success, although as yet the results furnished do not bear comparison with those obtained by Mr. Swan with the storage battery. Those who have spent any length of time under ground, especially in the very low workings which abound in coal mines, and at the high temperature which often prevails in the workings of deep mines, will have experienced the fact that any incumbrance may sometimes become very burdensome, and can well understand, therefore, that the weight and size of even the lightest form of battery with which an efficient light could be maintained for a sufficient length of time, may prove grave obstacles to its extensive employment. Moreover, as the electric light can afford no indication of the condition of the atmosphere in a mine-working, its employment may not allow of the safety lamp or some other testing appliance being dispensed with. But, even if used only as an auxiliary means of illumination in working places, such lights as those which Swan and others will supply, will prove very valuable, and especially so for exploring purposes, after accidents due to outbursts of gas, when the best safety lamps may be of little use, even if they continue to burn. Such electric lamps must indeed become formidable competitors of the Fleuss lamp (included in the recent Exhibition), which has, in conjunction with the portable apparatus for the supply of respirable air to explorers, already performed important service in rendering access to mine-workings possible where an ordinary lamp could not burn, and where the atmosphere was too foul to support life for any time.

The sudden escape into a mine-working of a very large volume of fire-damp, the accumulating pressure of which has at length overcome the resistance opposed to it, either by the coal or by the stone which forms the floor or the roof of the mine, and the outrush of which is sometimes accompanied by the ejection of very large quantities of disintegrated mineral, constitutes the most formidable danger connected with this associate of coal, because little or no warning is received of its occurrence, and because the volume of gas suddenly liberated is often so considerable that the most powerful ventilating currents are for a time inoperative, while their very action may be to distribute gas rapidly in the form of an explosive mixture with air, to distant parts of the mine-workings. The volume of gas suddenly set free varies very greatly: sometimes it is so considerable that, even with very powerful ventilation, the workings have not been restored to a safe condition for work, in regard to comparative freedom from fire-damp, until several days after the occurrence of the outburst.

That these sudden emissions of gas have been intimately connected with some of the most appalling disasters which have occurred in coal mines appears beyond question, and there is equally little room for doubt that the firing of shots, or use of gunpowder for blasting coal or stones in mines, has been, in many cases, intimately connected with those disasters.

The occurrence of a sudden outburst of gas is, however, not essential to the production of disastrous results by the firing of powder or other explosives in coal mines. The flame developed by the firing of a powder-shot may, without any favouring circumstances, be projected to a considerable distance beyond the face of the coal or stone in which it is fired, if, as is frequently the case, the force is insufficient to accomplish the fracture of the bore-hole in which the charge of explosive is confined, and the highly heated products of the explosion are entirely projected from the hole, as if the shot had been fired from a gun. Experiments upon an extensive scale made, on this head, by the Commission, have shown that the flame from a so-called *blown-out* shot may be projected to distances of thirty or thirty-five feet, in galleries similar to mine-workings or drifts, and if, as is frequently the case, the small debris of coal, which lies ready to hand in the working places is used to tamp the charge with, the volume of flame from a blown-out powder-shot is very greatly increased in length and volume, and may therefore easily extend to goaves, old working places, or cavities where a fire-damp- and air-mixture may be lurking. This is, however, by no means the only, or even the most prominent, danger which may attend the occurrence of a blown-out shot in even the best ventilated coal mine, quite independently of the possibility of a sudden release of a considerable volume of fire-damp during, and consequent upon, blasting. But before referring to what now appears to be well established as the chief general source of danger attending the use of explosives in coal mines, I must touch briefly upon the means available for searching for fire-damp, and for inspecting the workings of a mine, to ascertain that all is safe before men descend to work, or before shots are fired.

The first effect of introducing a Davy or other safety lamp into an atmosphere containing small proportions of fire-damp is to cause the flame to elongate, the extremity becoming narrow and more pointed as the proportion of fire-damp increases; when the latter approaches a porportion which produces with air an inflammable, and ultimately an explosive, mixture, a pale blue halo or cap is perceptible over the flame, and this increases with an increase in the proportion of gas, until the cage or gauze of the lamp is filled with flame. A Davy lamp of small proportions is generally preferred by the overmen or inspectors for gas-testing purposes; the flame is always reduced to small dimensions, so that slight alterations in size or form may be more readily observed. An experienced operator may identify so large a quantity as 2 per cent. of gas in the air of a mine, but even this is very doubtful, except in the case of exceedingly expert observers, who may perhaps succeed in thus detecting the presence of 1·5 per cent. of fire-damp.

It has, however, now been conclusively demonstrated to be of the greatest importance that responsible persons in coal mines should be furnished with reliable means for expeditiously detecting, without the exercise of any very special skill, smaller quantities of fire-damp than it is possible to identify with certainty, even by the exercise of great skill in the use of a safety lamp. Hence much interest and moment attach to the efforts which have been made from time to time by scientific men to devise sensitive and reliable fire-damp indicators. The late Mr. Ansell applied in several very ingenious ways some results of Prof. Graham's classical researches on the diffusion of gases to the construction of sensitive fire-damp detectors, which, however, did not justify the confidence at first placed in them. The same principles have since been applied, but apparently with no greater success, by several foreign inventors of so-called *Grisoumètres.* The late Dr. Angus Smith and Prof. George Forbes have proposed to detect and estimate the quantity of fire-damp in the air of a mine by ingenious applications of other important principles in physical science, and the acoustic indicator, lately exhibited by Mr. Blaikley, is a very pretty application of the principle utilised in a different way by Prof. Forbes. Various forms of eudiometrical apparatus have been constructed with the same object: the variations in the density of air due to the presence of different proportions of fire-damp have been made the basis of other gas-indicating apparatus; a test-lamp has been constructed to furnish a flame when burning alcohol, which is much more sensitive than the oil flame of an ordinary safety lamp; and an electro-photometric test apparatus has been devised by Mr. E. H. Liveing, which appears to have been the most thoroughly practical form of gas-indicator shown at the recent Exhibition.

The importance of being able to recognise very small proportions of fire-damp in air has become specially evident, since the fact has become thoroughly established, by recent careful and comprehensive investigation, that when fire-damp is present in the atmosphere of a mine, in proportions greatly below those necessary to produce a feebly explosive, or even barely inflammable mixture, it may yet constitute a most formidable source of danger, by its co-operation with the dust which exists, in more or less abundance, in every mine-working.

The fact that coal-dust adds considerably to the disastrous effects of fire-damp explosions, was noticed already more than 80 years ago; but Faraday and Lyell were the first to demonstrate, forty years ago, how important a part might be played by coal-dust, in aggravating and extending the destructive effects of fire-damp explosions. When investigating a serious explosion which occurred in the Haswell Colliery in 1844, they observed many signs of the coal-dust being partly burned, and partly subjected to a charring or coking action, by the fire-damp explosion. Their lucid published account of the evidence that coal-dust may play an important part in the effects produced by mine-explosions covers much of the ground gone over by recent workers and writers on the subject, and affords a curious illustration of the ease with which the work of the most illustrious men may be overlooked or forgotten, even by those who should be specially interested in informing themselves of the existing state of knowledge on the subject. Thus, several well-known French mining engineers published, many years after Faraday and Lyell's work, observations, as new, which were simply confirmatory of those philosophers' original statements and conclusions.

Messrs. Galloway and Friere Marreco, but especially the former, have added importantly to our knowledge of the probable behaviour of dust in mines on the occasion of explosions. Mr. Galloway, who performed experiments upon a considerably larger scale than had previously been the case, was certainly the first to enunciate the conclusion that a small proportion of fire-damp is essential to impart to a mixture of air and coal-dust the power of propagating flame, though he afterwards concluded that fire-damp is altogether unnecessary for the conveyance of flame, with explosive effects, by a mixture of dry coal-dust and air.

The more recent results of other workers in this direction have, however, conclusively demonstrated that while some very highly inflammable coal-dusts may, when raised and mixed with the air by the force of a blown-out shot, become inflamed, and carry flame to considerable distances, with a rapidity and violence of action similar to that of a fire-damp explosion, the extent to which flame is propagated, by most descriptions of coal-dust, in the complete absence of fire-damp, is very limited.

In a series of experiments which, after the calamitous accident in Seaham Colliery in the autumn of 1880, I was requested by the present Home Secretary to carry out with coal-dusts, it was conclusively established that the proportion of fire-damp required to be present in the air of a mine, to bring dust readily into operation as an explosive agent, when thickly suspended in the air, may be even decidedly below the smallest amount which a practised eye can detect by means of a Davy lamp. Various other points of interest were established by this series of experiments.

The more extensive experiments subsequently made by the Commission, in large mine galleries, demonstrated that with a very highly inflammable dust suspended in the air in which no trace of hydrocarbon gas was present, a blown-out shot could produce ignitions which would extend as far as the mixture of air with sufficient dust to maintain flame extended.

Important experiments upon a very large scale, which have recently been carried out by the Prussian Fire-damp Commission, at Neunkirchen, in the Saarbrücken district (see NATURE, vol. xxxi. p. 12, and vol. xxxii. p. 55), have thoroughly confirmed and also considerably extended these results.

It appears now to be well established that the considerable volume of flame and rush of gas produced by a blown-out shot is indispensable to the attainment with certainty of any of the dangerous effects of coal-dust. Inasmuch, however, as blown-out shot are of very common occurrence in blasting operations, it is evident that in dusty mines there is a frequent liability to the production of a more or less extensive ignition or explosion of coal-dust, at any rate when even only very small proportions of fire-damp exist in the air of the mine. It will be seen, therefore, that it needs not a sudden outburst or accidental liberation of fire-damp in considerable quantities to cause the flame which may be projected into the air by the firing of a powder-shot to bring about extensive explosions, or ignitions, spreading over large areas, and possibly communicating to distant accumulations of explosive mixtures of gas and air in old workings.

These most serious dangers, arising chiefly from the use of powder in coal mines, have received the anxious attention of the Commissioners, who have, in the first place, considered how far it might be practicable to prescribe effectual means for removing or counteracting the elements of danger presented by the existence of dust accumulations in mines where it may be impossible to guard against the distribution of small proportions of fire-damp through the air.

The possible substitution for gunpowder of other explosive agents which may be applicable to the kind of work performed by it in coal-mines, has naturally also received much attention. A reduction in the volume of flame produced by gunpowder when used as a blasting agent has been effected by modifications in its composition, but the best result attained until recently in this direction had not materially reduced the danger of using powder in the ordinary manner. Some promising results are, however, said to have been quite lately attained in Germany with a special powder produced by the original maker of the now celebrated cocoa powder, the publication of which is looked for with much interest.

Special forms of gun-cotton were prepared for use in coal in the early days of the improvements made in its preparation; but the large proportion of the inflammable and poisonous gas, carbonic oxide, which its explosion furnishes, prohibits its employment in this direction, even in the form of preparations coming under the head of *nitrated gun-cotton*, which yields comparatively small proportions of carbonic oxide.

Nitro-glycerine contains actually more oxygen than required for the complete burning of its constituents, carbon and hydrogen, and hence its detonation in the open air is attended only by the appearance of a lightning-like flash of light. When diluted with an inert non-combustible material, as in dynamite, its detonation raises to a high red heat the particles of mineral matter with which it is mixed, many of which are, therefore, projected in a glowing state, like a shower of sparks, if the dynamite be fired in a strong shot-hole. Even with Nobel's blasting gelatine, the latest and most powerful explosive, a blown-out shot may be attended by the projection of some glowing particles, either of the tamping or detached from the blast-hole.

The Commissioners have satisfied themselves by many experiments that an explosive mixture of gas and air may be exploded by the projection into it of such sparks, and that they may even occasionally produce ignition, when projected into air containing only a small proportion of fire-damp, but in which coal-dust is thickly suspended.

The outline which I have given you of the dangers attending the use of explosives in coal mines, and of the apparently unsurmountable difficulties attending any attempts to approach immunity from the two great elements of danger naturally existing in a very large proportion of coal mines, namely, fire-damp and dust, will probably lead you to the conclusion that there is but one effectual method of dealing with the serious question of accidents due to explosions in coal mines, namely, that of enforcing the exclusion of the use of explosives in coal mines.

In the House of Commons debate of June, 1878, Mr. MacDonald, while acknowledging that the provisions of the Coal Mines Regulation Act of 1872, for prevention of accidents through the use of gunpowder in fiery mines, had been productive of great good, insisted that these regulations were insufficient to guard against fire-damp explosions, and referred, in illustration, to the fact that the firing of the shot itself might liberate a large quantity of gas, which no previous inspection would discover. He urged in the strongest terms that, until blasting in any fiery mine were absolutely prohibited, there must be a continual recurrence of terrible disasters; and, in the debate which followed, there was a general consensus of opinion among the speakers most competent, from personal experience, to express a decided view on the subject (such as Mr. Burt, Sir G. Elliot, and the late Mr. Knowles), that blasting should be prohibited, at any rate in fiery mines. It was admitted that the cost of working coal would be much increased by the enforcement of the suggested prohibition, and the majority of competent witnesses examined afterwards by the Royal Commission maintained that the abolition of shot-firing in coal-getting must be attended by very formidable difficulties, and must, in fact, cause the closing of many pits.

I have shown that even the comparatively very small amount of fire-damp which may, at any rate occasionally, pervade the air in portions of mine-workings where thorough ventilation is most effectually provided for, and may escape detection, suffices to determine the production of a disastrous explosion, if, under these circumstances, a blown-out shot occurs where an accumulation of dust exists; and that it is even possible, in the complete absence of fire-damp, for a blown-out shot to give rise to an explosion in a very dusty working or mine, where the coal is of a specially inflammable and sensitive character. Such being the case, the fact cannot be ignored that last year's decision of the late Home Secretary—which raised consternation in many mining districts—to prohibit the firing of shots in any colliery within a period of three months after the existence of gas had been there reported (while the workmen were in any part of the mine), is far from affording the contemplated protection against disaster resulting from the use of explosives *in the ordinary manner*.

This most grave aspect of the question has received the anxious attention of the Commissioners, who would not have considered themselves justified in relinquishing their work until they had practically investigated, as far as in their power, any measure or suggestion appearing to afford promise of aid in furnishing definite replies to the following important questions:—

(*a*) Whether sufficiently efficient substitutes for explosives exist to warrant the assertion that their abolition need not interfere very materially with the reasonably profitable working of collieries;

(*b*) Whether, therefore, it is practicable to limit their use strictly to localities where the absence of every possible risk of explosion can be demonstrated; or

(*c*) Whether any modifications in the ordinary method of using explosives in mines can be so confidently relied upon to guard against, or overcome, certain dangers attendant upon blasting operations in collieries, that it may be practicable to clearly define and lay down certain conditions which will insure the safe use of explosives, either generally, or in all but special cases, which can be precisely defined.

As regards the first question:—The power and efficiency of recently improved mechanical appliances for bringing down coal or for driving headings or crossways, warrant the sanguine expectation that compressed air and even manual power may be, at no distant day, brought to bear so advantageously in mines where fire-damp occurs, as to render it no great hardship to dispense with the use of explosives in some of the work where at present they are considered indispensable.

The considerable and very rapid increase in volume which freshly-burned quicklime sustains when slaked, led, many years ago, to attempts to apply it to the bringing down of coal; but the idea did not assume a really practical form until Messrs. Sebastian Smith and Moore worked out a simple method of applying the lime so as to insure the effective operation of the disruptive force which it is capable of exerting, and to utilise the considerable heat, developed by the union of the lime with water, in the rapid generation and super-heating of steam in somewhat considerable quantity, thus supplementing, in an important manner, the force exerted by the expansion of the lime. The public has been made familiar, in last year's and this year's Exhibitions, with the general nature of Messrs. Smith and Moore's lime cartridges. The Commissioners witnessed their performances at Shipley Collieries soon after their successful elaboration, and the results of subsequent inquiries and experiments have convinced them that, for coal-getting, the lime process can be, to a large extent, substituted for powder, and that its employment, while securing comparative immunity from danger, is unattended by any important practical difficulties.

It has received extensive trial in many of our mining districts, and also on the Continent, and has already taken firm root in some parts of Staffordshire, Yorkshire, and Derbyshire. Its elaborators do not contend that it affords the means of dispensing with the use of explosives, or of specially powerful mechanical appliances, in the removal of stone, or even in some very hard coal; but it is certain that in many collieries, where the prevalence of fire-damp renders the use of the safety lamp imperative, the replacement of shot-firing by lime-cartridges, while unattended by any increase in the cost of getting the coal, would reduce the risk of explosions to those arising from carelessness, or from what should now become the very remote contingency of the use of unsafe or defective lamps.

The idea has been entertained that, by surrounding or covering the charge of powder in a shot-hole with some material which evolves vapour of water, or carbonic acid, when exposed to sufficient heat, these would be liberated by the firing of the shot in sufficient quantity and with sufficient rapidity to extinguish flame and sparks projected by it; but the authors of such suggestions have failed to realise the fact that the exposure of these substances to heat on the firing of a shot would be almost instantaneous, and would therefore leave, at any rate, the greater proportion practically unaltered.

It was suggested by me to the Commissioners that possibly the sudden liberation of carbonic acid, confined in the liquefied state, and placed either over or under the charge in a shot-hole, might prove effective in extinguishing flame and sparks, and a number of experiments have been made in this direction, with considerable, though not complete, success.

Dr. McNab was the first to put into practical execution the idea of using water tamping, in the form of a long cylinder filled with the liquid and placed over the powder charge; with the twofold object of extinguishing the projected flame and sparks, and of diminishing, by dispersion of the water in the immediate vicinity of the shot, the persistence of the powder smoke, which is a source of much inconvenience and loss of time. While it has been demonstrated that decided economy in time does result from the more rapid clearing of the air from smoke when the water tamping is used, many careful experiments conducted for the Commission have shown that no reliance could be placed upon the extinguishing power of water, applied in the way originally suggested by Dr. McNab.

In 1879 I suggested to the Commission a plan by which possibly the more violent explosives, of the dynamite class, might be safely and efficiently applied to the getting of coal, based upon the principle of distributing the force developed by the detonation of small charges over a considerable area through the agency of a column of water, within which the detonated charge was confined. This principle, which has since received important applications in connection with military service, appeared applicable to effect a modification of the shattering action, which renders the violent explosives inapplicable to coal-getting, when used in the ordinary manner, their effects being thus assimilated to those of powder, while the sparks and highly-heated gases projected by a blown-out shot might be effectually quenched by the water which would envelope them at the instant of their projection.

Experiments carried out at Wigan in 1880, demonstrated that the coal brought down by small charges of dynamite inclosed in water compared very favourably with the best results furnished by full powder charges, and these results have been fully confirmed by trials since carried out for the Commission in South Wales. Absolute immunity from danger of the ignition of an explosive gas-mixture by a blown-out shot of dynamite or similar explosive agent was not found to be secured by this system of blasting; such was the case, however, then the blown-out shot was projected into air containing fire-damp in proportions approaching that of an explosive mixture, and in which a very inflammable coal-dust was thickly suspended. It has also been found, in the Commissioners' experiments, that the superposition of the water-tamping, according to Dr. McNab's original plan, over a dynamite charge, appears to afford security against the ignition of a dust-laden mixture of air with a somewhat considerable proportion of gas.

Even while actively engaged in the completion of their Report, the Commissioners are still pursuing this subject experimentally, with the desire of furnishing, as far as in their power, decisive and thoroughly reliable data regarding the amount of security which appears to be afforded, by these methods of working, against the most prominent and prevalent sources of danger in connection with the use of explosives in coal mines; and—while I have been engaged upon this address—a still more simple method of applying water to counteract the dangers arising from blown-out shots has suggested itself to Mr. Galloway,—preliminary experiments with which have furnished most important results.

I have now attempted to give you an outline of the progress made within the last few years towards a thorough comprehension of the nature and causes of those dangers which most prominently direct public attention to the perils of the miner's calling—and of the advances already made, and rapidly progressing, towards the provision of the miner with really safe and efficient underground illumination, with efficient substitutes for explosives for a large proportion of the work connected with coal mining, and with safe methods of using explosive agents where these cannot be dispensed with; so safe that the terrors which have attended blasting in mines may be confidently expected speedily to fade away. I venture to think it will have demonstrated that we have made most satisfactory and important progress in all of these several directions, thanks to the labours of professional associations, of scientific and practical experts, and, I think I may also say, thanks to the exertions of the Royal Commission on Accidents in Mines.

I have been led to refer more fully than I had first intended to the work performed by the Royal Commission—the results of which, in detail, will shortly be in the hands of the public—because I felt sure that the members of the Society of Arts would take a most lively and sympathetic interest in the labours of men, who have not allowed themselves to be discouraged by unjust attacks and ignorant criticism, from endeavouring to carry to a useful termination the arduous work which they cheerfully took upon themselves.

The Commissioners have been silent while hard things have been said of them; but it were idle to deny that they have acutely felt the injustice reflected upon them by some writers in the public Press who, while posing as judges or philanthropists, have not earned for themselves, by knowledge acquired, or by work performed, the right to criticism.

Thirty years' personal experience of the work of experimental Committees has taught me that *ad interim* reports are not unfrequently worse than valueless, and this would certainly have been the case had the Commissioners attempted to make any so-called progress reports, because conclusions, or suggestions, might have been put forward in them which would have had to be afterwards recalled, or incomplete data given, which might have been misleading, and, therefore, even dangerous.

As regards the question of the unsafe nature of certain so-called safety lamps, however, I have pointed out that the Commissioners, just five years ago, reported to the Home Secretary in no hesitating terms, in the belief that their statements would have been published,—and it is no fault of theirs that the public was not informed of their strongly-expressed conclusions on this subject, but has been, on the contrary, recently told in the *Times* by a well-known mining engineer that the results of the Royal Commission's labours "have not even extended to the official condemnation of the known unsafe lamps."

The daily journals have at any rate chronicled the activity of the Commission by recording the dates and *locale* of their frequent meetings,—and have been cognisant, therefore, of the fact that their place of work was easily accessible. This being so, it is somewhat matter for surprise that the writer of very condemnatory paragraphs in an editorial article, suggested by correspondence published in the *Times* last June, should not have cared, in the first instance, to inform himself, however imperfectly, of the kind of work upon which the Commission was engaged, and to take that opportunity of seeking some little correct information on the subjects with which his graphic pen was directed to deal. Had he done so, he would scarcely have instructed the public that "a huge majority of colliery accidents arise from explosions;" that "coal mines generate an explosive gas, which, when collected in a quantity, and exposed to a flame, ignites, and blows into fragments the workings in which the vapour and flame meet;" "that every coal mine has its explosive gas," or that "often the miner has opened the door of his lamp to light up the cavern, already perhaps darkening with the heaviness of a gas-laden atmosphere." I will do him the justice to believe that he would not have felt disposed, after even very brief inquiry, to indorse as "not exaggerated" the declaration of the "strenuous and benevolent correspondent," Mr. Ellis Lever, "that the delay in the issue of the Commission's Report was "to the eternal discredit of Royal Commissions."

After all, however, it rests entirely with the public Press to decide for itself whether the ends it has in view are such as to render it desirable to seek for correct information before administering public condemnation.

But, with a public official, especially when connected with the very Department of State most directly concerned in the work of the Commission, the case is very different; and it is scarcely to be credited that the gentleman intrusted with reporting to the Home Secretary upon the circumstances attending the explosion last summer, at Clifton Hall Colliery, should not have thought it worth his while to ascertain, by inquiry, which could not but have been of immediate service to him, whether the delay in the completion of the Commissioners' Report was "unaccountable."

To this Society, which has always distinguished itself by its encouragement of earnest workers, and by its just judgment of their labours, I have ventured, as one of its members, to make these comments, which could not be uttered by me in my capacity as a member of Her Majesty's Commission, whose duty it is simply to report the results of their labours when they have, to the best of their judgment, fulfilled the duties imposed upon them.

SOCIETIES AND ACADEMIES

London

Royal Society, November 19.—Abstract of "Report on a Series of Specimens of the Deposits of the Nile Delta, obtained by the recent Boring Operations." By J. W. Judd, F.R.S., Professor of Geology in the Normal School of Science and Royal School of Mines. Communicated by order of the Delta Committee.

Neither of the borings made for the Royal Society, under the superintendence of the engineers attached to the army of occupation in Egypt, appears to have reached the rocky floor of the Nile-Valley, nor do the samples examined show any indication of an approach to such floor. What were at first supposed to be pebbles in one of the samples from Tantah, prove on examination to be calcareous concretions ("race," or "kunkur"). Nevertheless, these borings appear to have reached a greater depth than all previous ones in the same district with one or two exceptions. The deepest of the three borings now reported upon have been carried to 73 and 84 feet respectively.

The samples from these borings, like those examined by Mr. Horner, show that the delta-deposits all consist of admixtures, in various proportions, of blown-sand and alluvial-mud. I can find no evidence to support the suggestion made by Sir J. W. Dawson, F.R.S., from a hasty examination of the specimens, that "at a depth of 30 or 40 feet the alluvial mud rests on desert sand;" on the contrary these borings, like those of older date, show that the deposits of the Nile Valley consist of a succession of different beds in some of which sand, and in others mud, forms the predominant constituent.

The *sands*, when separated from the mud by washing, are found to be made up of two kinds of grains, the larger being perfectly rounded and polished, while the smaller, on the contrary, are often subangular or angular.

The larger and well-rounded grains may be described as microscopic pebbles; their surfaces are most exquisitely smoothed and polished, and their forms are either globular or ellipsoidal. In size they vary greatly, being occasionally as large as a small pea. They only very occasionally exhibit traces of deposits of iron-oxides upon their surfaces.

Embedding these grains in Canada balsam, and examining them by transmitted light, with the aid of the polariscope, we are in nearly all cases enabled to determine their mineral characters. The majority of the grains consist of colourless quartz, though occasionally rose-quartz, amethystine quartz, citrine, and smoky quartz also occur. This quartz exhibits unmistakable evidence of having been derived from granitic rocks; it is constantly seen to be traversed by bands of liquid- and gas-cavities, and very frequently contains numerous black hair-like inclusions (rutile?). Much more rarely we detect grains of quartz which consist of aggregates of small crystals, and are evidently derived from metamorphic rocks. With the pure quartz grains we find also a considerable number of rounded particles of red and brown jasper and of black Lydian stone, with fragments of silicified wood.

But in addition to the different varieties of quartz, particles of felspar are found in considerable abundance among these large rounded grains. What is very remarkable about these felspar-grains is the slight traces of kaolinisation which they exhibit; they are, in fact, almost as fresh and unaltered as the grains of quartz themselves. Ordinary orthoclase and microline are abundant, while plagioclase felspar is comparatively rare. With the rounded grains of quartz and felspar, a few examples of hornblende and other minerals, including jade, also occur.

But far greater is the number of mineral species represented in the smaller subangular and angular sand-grains. In addition to the minerals already mentioned, I have recognised several varieties of mica, augite, enstatite, tourmaline, sphene, dichroite (cordierite), zircon, fluorspar, and magnetite.

The *mud* is a much more difficult material to study the mineral characters of than the sand, owing to the extreme minuteness of its particles. It is a ver striking fact, however, that kaolin, which constitutes the predominant ingredient of clays, appears to be almost absent from these Nile-muds. Chips and flakes of quartz, felspar, mica, hornblende, and other minerals, can be readily recognised, and it is often evident that the unaltered particles of such minerals make up the greater part, if not the whole mass, of the fine-grained deposits. The mineral particles are, of course, mingled with a larger or smaller proportion of organic particles. Frustules of *Diatomaceæ* occur in these muds, as was pointed out by Ehrenberg, but unless special precautions were observed in collecting the samples it would be unsafe to draw any deductions from their presence.

The striking peculiarities of these sands and muds of the Nile-Valley appear to be capable of a simple explanation. In countries where rain falls and vegetation abounds, water charged with carbonic acid is constantly tending to break up the compound silicates; the silicates of the alkalies and the alkaline earths being decomposed and their constituents removed in solution, while the silicate of alumina becomes hydrated, and is carried away in suspension by water in the form of kaolin. In this way, the felspars and nearly all other compound silicates are affected to such an extent that in most granitic and metamorphic rocks they show evidence of extensive "kaolinization," while the clays derived from them are made up for the most part of crystalline plates of kaolin. But in a rainless country, like Northern Africa, none of these agencies will operate, and the disintegration of the solid rocks is effected by mechanical means; the most potent of these mechanical agents are the heat of the sun, causing the unequal expansion of the minerals which build up the rocks, and the force of the wind, producing constant attrition of the disjoined particles.

This being the case, it will be readily understood that the coarser sand-grains will include felspar and other minerals in a nearly unaltered condition, while in countries where the chemical agents of the atmosphere come into play, such particles would be more or less completely converted into kaolin. In the same way the mud, instead of consisting of scales of kaolin originating from chemical action, will be formed of particles of the chemically unaltered minerals reduced to the finest dust by purely mechanical agencies.

The chemical analyses which have been made of these Nile muds entirely support these conclusions. Instead of containing a considerable proportion of combined water, as do all the ordinary clays, their composition is that of a mixture of anhydrous minerals.

But there is fortunately a kind of evidence, derived from chemical analysis which is of the greatest value from its bearing on the questions we are now discussing—that, namely, which is derived from a study of the composition of the Nile-waters.

It must be remembered that the Nile is a river of a very peculiar and exceptional character. The last tributary which it receives is the Atbara, which falls into it in lat. 17° 38′ N.; from that point to its mouth, in 31° 25′ N. lat., the river does not receive a single affluent; for a distance of 1400 miles it acquires no fresh supply of water except what is brought to it by superficial torrents after heavy rains in Lower Egypt. It has been clearly demonstrated that, after receiving the Atbara, the Nile undergoes a continual diminution in volume in its course through Egypt. This is no doubt in part due to percolation of the water through the delta-deposits, and in part to the water being drawn off in canals for purposes of irrigation; but a large part of this diminution in volume must certainly be ascribed to the great evaporation which must be going on from the surface of the river during the last 1400 miles of its course.

Although we shall not be able to calculate the exact loss of the Nile by evaporation in the course of 1400 miles through one of the hottest and driest regions of the globe, yet we cannot doubt that this loss is enormous. Now the effect of this constant evaporation must be to concentrate the saline matters held in solution, and we might therefore anticipate that the waters of the Nile in Lower Egypt would contain an exceptionally high percentage of saline matters in solution.

But what are the actual facts of the case?

According to the analyses of Dr. C. Meymott Tidy, the Nile contains only a little more than one-half of the proportion of soluble materials which exists in the Thames, the Lea, the Severn, or the Shannon!

A little consideration will show, however, that this startling and seemingly anomalous result is capable of simple and easy explanation. The substances dissolved in the water of rivers is of course derived from the materials composing the rocks of the river-basin, through the action of water holding carbonic acid or other acids in solution.

Hence we are led by the study of the composition of the Nile water to the same conclusion as was reached by the study of microscopical characters of the muds and sands of the delta, that while in the rainy districts of the temperate zones the disintegration of rocks is mainly effected by chemical agencies, in the rainless areas of the tropics the same work is almost exclusively effected by mechanical forces.

The products of these two kinds of action are, however, essentially different. In the former case we have formed crystals of kaolin, which constitute the basis of all the true clays, a large quantity of lime, magnesia, iron, soda, and potash salts with silica passing into solution; while, in the latter case, the several minerals of the rock are simply reduced to fragments of varying size and form, and but little matter passes into solution.

The whole of the observations described in the present report are in entire harmony with this explanation. The comparatively unaltered condition of the felspars and other complex silicates in the sands; the absence of kaolin from the muds, and the presence of the chips and flakes of the unattacked minerals in the muds; and finally the small quantity of dissolved matter in the Nile-water, in spite of the enormous concentration it must have undergone by evaporation—all point to this same conclusion.

In the estimates which have been made of the rate of subaërial denudation in different parts of the globe, it has usually been assumed that this action is similar to what is seen taking place in our own country and in North America. But the observations detailed in this report prove that in rainless tropical districts, where little or no vegetation exists, the disintegration of rocks, though not, perhaps, less rapid than in temperate climes, is different alike in its causes and in its products.

It has often been pointed out by chemical geologists that metamorphic action could not have produced many of the schists from sedimentary rocks, for the former are rich in potash, soda, and other materials which have been dissolved out from the latter during the disintegration of the rock-masses from which they were derived. The recognition of a kind of action whereby great masses of sedimentary materials can be produced, rich in those substances which are usually removed in a state of solution, is not destitute of interest at the present time, when the question of the origin of the crystalline schists is one that presses for solution.

PARIS

Academy of Sciences, November 30.—M. Jurien de la Gravière, Vice-President, in the chair.—The Vice-President announced the death of the President, M. Henri Bouley, who died on the morning of the same day. The speaker referred in warm terms to the career of M. Bouley, his entire devotion to science, and the courage with which, although suffering from a fatal disease, he continued to the last to fulfil the duties of his office.—Obituary notices of M. Bouley: by M. Hervé Mangon, in the name of the Academy of Sciences; by M. A. Milne-Edwards, in the name of the Natural History Museum; by M. A. de Quatrefages, as Vice-President of the Acclimatisation Society; and by M. Fremy, Member of the Academy.—As a mark of respect for its late President, the public meeting of the Academy was immediately adjourned.

BERLIN

Physiological Society, October 30.—Prof. Zuntz spoke on the apnœa of the fœtus and the cause of the first respiration, setting forth the present state of the question, and then passing to consider the assertion of Prof. Preyer, who, by experiments on rabbits and guinea-pigs, sought to prove that it was not the change in the gas of the blood which was the cause of the first respiration, but a stimulus exercised on the integument. Prof. Zuntz had quite recently, in conjunction with Dr. Cohnstein, made observations on a new-born lamb that, connected by the umbilical cord with the ewe, came into the world completely apnœic, and, notwithstanding that the most varied stimulations were exercised on the skin, continued apnœic for ten minutes long, though in all other respects these stimulations were normally responded to. Not till the placenta had detached itself did the respiration begin. This observation proved with all certainty that apnœa was dependent on the sufficient supply of oxygen, and that the first respiration was induced by a deficit of oxygen. They therefore repeated the experiments of Prof. Preyer, and came to the conclusion that under them the circulation of the blood always suffered disturbance in consequence of the pressure exerted, whereby the supply of oxygen to the fœtus was impaired, and that the fact which Prof. Preyer adduced in support of the accuracy of his view, namely, that the blood of the umbilical vein always appeared of a bright scarlet red, served exactly to disprove it. The brighter blood of the umbilical vein was, accordingly, an argument of a disturbance in the circulation of the blood, in consequence of which less arterial blood reached the fœtus, and, notwithstanding its greater saturation of oxygen, the blood was, therefore, unable, on account of its deficient quantity, to convey the requisite amount of oxygen to the whole blood. The respiratory centre in the brain thus got supplied with blood poorer in oxygen, and when a stimulation of the skin was superadded the first respiration ensued. In the case of the less excitable brain of the fœtus it was necessary that the outward stimulation should supplement the deficiency of oxygen. In the case of the normally born, however, the detachment from the placenta and the absolute want of fresh oxygen sufficed to stimulate the respiratory centre to activity. In the case of the adult, finally, with excitable brain, a slight reduction of oxygen was itself sufficient to excite respiration.—Referring to the beautiful discovery by Mr. Haycroft, of the fact that the ferment of the saliva in the leech prevented coagulation, Prof. Zuntz recommended the use of this ferment of the leech in measurements of blood-pressure, with a view to avoiding coagulation. This substance had the advantage over all other preventives of coagulation, that in no respect had it any toxic effect. Into the tube conjoining the artery of the animal examined with the manometer of the kymographion a T-tube was intercalated, and by its means a cubic centimetre of the ferment of the leech was squirted per hour into the separate fluid. This was sufficient for the marking of curves of blood-pressure for seven hours consecutively, without the least trace of coagulation.—In view of the divergence of opinions prevailing regarding the alimentary value of the peptones—some maintaining that peptone was used as an alimentary deposit in the body, while others considered that only the albumen absorbed as such was capable of being deposited, the peptones getting, on the contrary, further decomposed—Prof. Zuntz had a number of feeding experiments instituted with peptones. A somewhat long series of experiments was executed on a little dog, first with meat, then with peptone furnished from fibrine, next with albumose substances or propeptones, and, further, with lime. The experiment was arranged in such wise that the dog, along with equal quantities of fat and starch, received daily the like amount of nitrogen. The quantity of secreted nitrogen was daily determined, and thereby the deposit of nitrogen ascertained. The dog first got meat for some days, then peptones for some days, next thereafter meat again, and, following thereon, albuminose substances; this in turn was succeeded by meat days again, then lime days, and, finally, meat days anew. The deposit of nitrogen was now found to amount to—(1) with meat diet, 0·502 grammes nitrogen daily; (2) with peptone, 0·584 grammes; (3) with meat, 0·513 grammes; (4) with propeptone, 0·70 grammes; (5) with meat, 0·46 grammes; (6) with lime, – 0·5 grammes; (7) with meat, 0·48 grammes nitrogen. Meat feeding, accordingly, yielded about the same quantity of nitrogen deposit on each occasion of its being used; in the case of feeding with peptone and propeptone the nitrogen deposit was somewhat greater than in the case of meat-feeding, a result explained by the fact that all the nitrogen of meat did not belong to the albumen, but in part appertained to the nitrogenous bases, which could yield no nitrogen deposit. In the case of lime-feeding, on the other hand, a loss of nitrogen for the body was the result. Prof. Zuntz next had a further series of feeding-experiments performed with the peptones occurring in trade. The dog in question received only fat in addition to the nitrogenous nutriment. In the first days, with meat-feeding, a deposit of nitrogen, to the amount of 0·2 grammes daily, was the result; under feeding with Kämmerich's peptone following thereon, the daily deposit of nitrogen was – 0·4 grammes; the meat days, next succeeding, again yielded 0·2 grammes nitrogen in deposit, while the feeding, thereafter ensuing, with Koch's peptone again showed – 0·4 grammes nitrogen in deposit. The series was closed by meat-feeding, which produced 0·3 grammes deposit of nitrogen. The marketable peptones were therefore, notwithstanding the like supply of nitrogen, incapable of producing a deposit of albumen; on the contrary there rather occurred a loss of corporeal albumen, not so great, however, as when the like quantity of nitrogen was partaken in the form of lime. A series of experiments was finally carried out with the marketable peptones on a dog which for a considerable length of time had been fed only with rice and fat, and had thereby been very much reduced in strength. In this case the first day of feeding with Kämmerich's peptone produced a deposit of nitrogen to the amount of 0·6 grammes; in the following days this deposit was less; and soon the nitrogen showed itself at equilibrium. Under feeding with Koch's peptone, too, the animal, which was very much reduced, was maintained at equilibrium in respect of nitrogen.—Dr. Weyl communicated the results of his further investigation into the constitution of the derivatives obtained from cholestearine, which, at a meeting of the Society before the vacation, he had declared to be terpenes. He endeavoured to determine the molecular weight of those carbo-hydrates which, according to the nature of terpenes, had the composition $(C_5H_8)^n$. The vapour density, determined according to the method of Victor Meyer, showed itself in the lead bath not normal. It corresponded with the composition C_5H_8, thus indicating decidedly that a dissociation had set in during the process of heating. Other terpenes also, such as turpentine oil and camphor, yielded results which were not normal and showed a dissociation into the radical C_5H_8, a circumstance which likewise argued the terpene nature of cholestearine. Dr. Weyl was able, finally, to demonstrate the connection of cholestearine with the terpenes by showing that the latter very beautifully produced the well-known cholestearine reaction. Further experiments with a view to determining the vapour density in a vacuum would perhaps yield the molecular weight of these interesting carbohydrates.

THE NORWEGIAN NORTH ATLANTIC EXPEDITION—CRUSTACEA

The Norwegian North Atlantic Expedition, 1876-78. *Zoology*. XIV. *Crustacea*, IA. and IB. By G. O. Sars. 4to, pp. 280, with 21 Plates and a Map. (Christiania, 1885; London: Sampson Low and Co.)

NO better evidence can be adduced of the growing influence exercised by the cultivation of natural science than in the more ready tendency displayed by the Governments of various countries to promote expeditions for scientific purposes, and a greater willingness to furnish the necessary means for the publication of the results in a satisfactory manner.

Nor can we fail to look back with a feeling of pride to the work accomplished by our own early naturalists, from the days of Banks and Solander (1768-77) to the voyage of the *Beagle* (1844-46), which the "Journal" and "Observations" of Charles Darwin have for ever rendered famous; and down to the recent magnificent results of the *Challenger* Expedition, which its grand publications are rapidly unfolding to us.

The prospectus of the "Norwegian North Atlantic Expedition" was announced in NATURE, June 2, 1881 (p. 108), and the memoir on the *Gephyrœa* by Danielsson and Koren was noticed September 29, 1881 (p. 506).

The present memoir by Prof. G. O. Sars, on the Crustacea, occupies two quarto parts, illustrated by upwards of 600 figures drawn by the author himself from the actual specimens by means of the camera lucida, "thus affording a sufficient guarantee for their accuracy."

One cannot fail to be struck by the results obtained by the author in so comparatively limited an area, over part of which, at least, other naturalists must have already worked. The map embraces the ocean from the North of Scotland to Spitzbergen, and from Norway to Iceland and Greenland; or from 55° to 80° north latitude, and from 40° east to 25° west longitude.

"To avoid repetition in stating localities," writes Prof. Sars, "I have given a list of all the stations at which the dredge or the trawl was used, along with the date, position of the vessel, depth, bottom-temperature, nature of the bottom, and character of the apparatus. With but very few exceptions crustaceans were obtained at all these stations. Moreover, pelagic forms were collected with the surface-net at many other stations not included in the list. At the coast stations enumerated in conclusion, a smaller dredge was made use of, either from a boat, or from the ship when lying at anchor.

"The stations enumerated in the list have all been accurately set off on the map in which the curves of depth for 500, 1000, 1500, and 2000 fathoms are drawn as dotted lines. In the map will also be found a more strongly-marked curve, indicating the boundary-line between the cold and temperate areas, determined from the observed bottom-temperatures. This curve also forms the natural limit of the ocean valley—reaching 2000 fathoms in depth, and "filled at the bottom with ice-cold water—which shelves from the Polar Sea to the tract between Norway and Iceland, and, in the form of a narrow wedge, terminates in the so-called 'Færœ-Shetland Channel,' where it is cut off by a narrow transverse ridge from the great depths of the Atlantic" (p. 2).

Of the list of results of work performed at the eighty-six stations, either by means of the dredge, the trawl, or with "swabs," sixty give a bottom temperature of from 0° C. to 2° C. only; the highest reading being 7° C., in 237 fathoms close to the coast of Norway; whilst the average temperature at the bottom is only 2°·3 C., or 3° above freezing-point.

The deepest dredging recorded in Sars' list is 1861 fathoms, with a bottom-temperature of 1°·2 C.; but at p. 159 he mentions that *Harpinia abyssi* was obtained from a depth of 2215 fathoms.

In treating of the crustacean fauna of this region Prof. Sars has not included forms previously established as belonging to the Norwegian *littoral* fauna. Such forms will be fully treated of elsewhere, in a work on the Crustacea of Norway, to be shortly executed by the author.

Some idea may be formed of the extreme Arctic facies presented by the Crustacea inhabiting the depths of this cold-water area of the North Atlantic by noticing the relative proportions of species appertaining to each order recorded by Sars.

Thus of the BRACHYURA 1 species only is recorded (*Scyramathia Carpenteri*, Norman) from 220 fathoms; a form described and figured in Sir Wyville Thomson's "Depths of the Sea" (p. 175). From the slight development of the eyes and their light-coloured pigment it was probably blind, as is the case commonly with the crustacea from great depths.

Of the ANOMOURA only 1 species (*Eupagurus tricarinatus*, Norman) was taken in about 98 fathoms.

Four species of CARIDEA are described, the largest of these, *Sclerocrangon salebrosus* (Owen), appears to be widely distributed in the northern seas, ranging from 100 to 459 fathoms; but off the coast of Kamschatka, according to Tilesius, it is found abundantly in shallower water, and serves as an article of food to the natives. It ranges from Norway to Spitzbergen (p. 25).

Of the two species of *Bythocaris*, *B. leucopis* G. O. Sars, and *B. Payeri*, Heller, it is interesting to notice that the young of this Caridian do not pass through the usual post-embryonic metamorphosis, or larval stage, but on quitting the remarkably large ova, they are seen to be provided with the full number of appendages observed in the parent. All the species are true deep sea forms (1110 fathoms!), the eyes being unusually small and imperfect.

The next form, *Hymenodora glacialis*, has legs, as in the Schizopods, with a well-developed natatory branch (exopodite) attached to the outer side of the second joint. The eyes are small and imperfectly developed. It would seem to lead a semi-pelagic life, but it was taken at a depth varying from 452 to 1862 fathoms in the cold area.

Of the Schizopoda five species of "opossum shrimps," *Mysidæ*, were taken: *Erythrops gracilis* in from 263 to 498 fathoms, and *Pseudomysis abyssi*, Sars, from 1110 to 1280 fathoms! *Boreomysis nobilis*, 6 mm. long, was taken off the north-west coast of Spitzbergen, 80° N. lat. in 450 fathoms. The most remarkable of these deep-sea *Mysidæ* is the *Boreomysis scyphops*. "The eyes in this species are remarkable alike in character and form, their outer surface being, instead of convex, considerably hollowed, which gives them a well-nigh calyciform appearance. They are attached comparatively close together, in a vertical position, with the convex surface turning in and the concave out! Of any specific ocular pigment, or indeed of any visual elements whatsoever, no trace could be detected in the recently-taken specimens, and subsequent examination fully confirmed the absolute want of such" (p. 57).

One species of *Cumaceæ*, *Diastylis nodosa*, was obtained in 125 fathoms at Ice Sound, Spitzbergen. It has no trace of eyes, the ocular tract being *quite flat*, nor can any pigment or other visual element be seen (p. 63).

Of the ISOPODA 18 species are recorded, including members of the families *Apseudidæ*, *Tanaidæ*, *Anceidæ*, and *Arcturidæ*.

Sphyrapus serratus, Sars, is one of the most remarkable of these, both in the form of its body, of which 13 somites can be seen, and 19 paired appendages (Plate 21). The first pair of legs springing from the posterior part of the cephalic segment, are like the chelipeds in more highly-developed Crustaceans (Decapods), exceedingly powerful prehensile organs. The second pair of legs are as long as the entire body, and are flattened and armed with powerful spines, as if intended to serve as fossorial organs. Five pairs of slender walking appendages follow, succeeded by five pairs of biramous swimming-feet and a pair of long multiarticulate caudal appendages, also branched. The whole appearance of this creature is most remarkable, but it has a strong resemblance to *Apseudes*.

Sphyrapus serratus occurs in the open sea between Norway and Iceland, and also west of Spitzbergen, varying in depth from 1163 to 1333 fathoms, and ranging from the 63rd to the 78th parallel of latitude. Eyes, in a strict sense, are entirely wanting; no trace of visual elements whatever could be detected (p. 68). Of the *Tanaidæ*, three species, belonging to as many genera, were taken; all in deep water and all blind (Plate 7). The colour of these forms, as a rule, is a uniform white.

Not least remarkable among the Isopoda are the *Anceidæ* (Plate 8), most insect-looking of all the Crustacea! "The so-called mandibles (Fig. 6), which, however, as pointed out by Prof. Dohrn, both as regards their position relative to the buccal orifice and their general development, can scarcely be held to be homologous with the mandibles in other Crustaceans, are attached to the foremost margin of the head, and project freely in front of it, admitting of being moved horizontally one towards the other, like a pair of forceps" (p. 88). The larvæ (Praniza) are even more insect-like in appearance than the adult forms (see Plate 8, Figs. 13 and 27). The females of these forms are probably parasitic upon deep-sea fishes, or other large deep-sea animals. The males and larvæ of three species described were dredged from 72° to 78° N. lat., in from 658 to 1215 fathoms; they are all blind forms.

Many beautiful forms of *Arcturidæ*, *e.g.* *Arcturus baffini*, *A. tuberosus*, *A. hystrix*, &c., are figured and described. *A. baffini* was taken as far north as the west coast of Spitzbergen in 416 fathoms, and *Glyptonotus megalurus*, an allied form ranging from 63° to 78° N. latitude, inhabits depths of from 1081 to 1710 fathoms in ice-cold water!

Another strange form is the *Eurycope gigantea*. In this isopod the 2nd pair of antennæ are prodigiously developed, being more than four times the length of the whole body.

The *Amphipoda*, 45 in number, form by far the largest group of Crustacea obtained by the Expedition.

Harpinia abyssi (G. O. Sars, Pl. 13, Fig. 5) was obtained from a depth of from 350 to 2215 fathoms! It is distributed from 63° to 75° N. latitude and from 16° E. long. to 12° W. long. *Epimeria loricata*, a very handsome form, with spinose segments (Pl. 14, Fig. 2) was dredged near Spitzbergen in 260 fathoms. *Oidiceros macrocheir* dredged off Jan Mayen in 1004 fathoms was destitute of eyes (Pl. 15, Fig. 4). *Melita pallida*, another blind form (Pl. 15, Fig. 1), was found inhabiting deserted *Teredo*-burrows in an old piece of wood, dredged up from a depth of 1333 fathoms off the west coast of Spitzbergen.

Several *Caprellæ*, attached to hydroid polyps, were brought up in the dredge from a rocky bottom at 180 fathoms.

Eucheta norvegica, a copepod of the family *Calanidæ* was taken at no fewer than twelve stations at *very considerable* depths, whereas the surface-net at these localities, even when sunk considerably below the upper layer, never contained a single example.

Of the *Cirripedia*, *Scalpellum strömii* was dredged in 870 fathoms attached to the tubes of *Tubularia indivisa*. Five other species were obtained, namely, *S. cornutum*, *S. hamatum*, *S. vulgare*, *S. angustum*, and *S. striolatum*, the last attached to sponges. These are mostly white, and were collected from numerous localities and from varying depths.

A remarkably slender tubular form of *Balanus crenatus* was met with in 21 fathoms north of Beeren Island.

A Rhizocephalon (fam. *Peltogastridæ*) named *Stylon Hymenodore* attached parasitically to the abdomen of *Hymenodora glacialis* (dredged from a depth of 1861 fathoms) completes the list of forms described.

Thirteen additional species are referred to in a supplement as noticed by other writers since the present work was handed in to the scientific editor.

One is struck by the fact that of the 82 species of crustacea obtained by Sars, at these great depths in this ice-cold area, 61 are considered to represent distinct genera! Can it be that the conditions of life are here so hard, and the struggle for existence so severe, that each individual peculiarity becomes intensified, and that not only the cold, but the *darkness* may produce considerable changes in their organisation? Absence of *colour* and absence of *sight* are the prevailing characteristics exhibited by nearly every species; whilst the loss of eyes seems to stimulate the development of all the tactile organs to supply their place, so that we find the same idiosyncrasies of structure manifested in these depths of the ocean as have been observed in the Crustacea of the American and Austrian caves, and from the dark underground waters of various parts of the world.

We should fail in our duty to the author and also to the scientific reader did we omit to point out for high commendation the admirably-prepared plates which accompany Prof. Sars' Memoir, all the details of which are most beautifully and accurately rendered.

And lastly, but by no means the least meritorious feature of the work, is the generous concession made to English and American scientific readers, by the kindness of the Swedish Government, who have caused this Memoir to be printed throughout in a double column, the left hand of every page being printed in Swedish and the right hand in English.

Much praise is also due to the editor and author for the careful manner in which the English portion of the work has been passed through the press, and for the very great care bestowed on its translation from the original Swedish.

CHARLES DARWIN

Charles Darwin. By Grant Allen. "English Worthies," Edited by Andrew Lang. (London: Longmans, Green, and Co., 1885.)

Charles Darwin, und sein Verhältniss zu Deutschland. Von Dr. Ernst Kraus. Darwinistiche Schriften, Nr. 16. (Leipzig: Ernst Günther, 1885.)

IT is a curious illustration of the change which has passed over the English mind, that already the name of Darwin should head the list of a projected series of popular books, not on eminent men of science, but on "English Worthies." This first member of the series is, as might have been expected from its authorship, a pleasing and favourable specimen of a kind of literature for which the public appear to entertain so keen a relish. For it is not only clear and picturesque in style, but is also evidently written *con amore*. Indeed, it was impossible for any man of common sense or common sensibility to have come into any kind of relation with Mr. Darwin, without being stirred by feelings of hero-worship, and Mr. Allen's reverential love for the hero is a natural tribute fittingly rendered to the lofty nature and mighty influence for whose loss the universal grief is still so fresh.

As a biographical sketch the little volume is decidedly a success. It gives in brief compass and good language the history of Mr. Darwin's antecedents, of his life and work, of his relation to contemporary thinkers, and of his presumable influence upon subsequent thought. All of which is done without losing sight of the desirability, in a popular treatise, of upholding the element of romance—a kind of treatment to which the character, the life, and the work of Darwin unite in lending themselves, as it were, by nature.

In his review of the course of thought upon the theory of evolution prior to Darwin, Mr. Allen is judicious; and his speculations upon the probable position of this theory at the present time if Darwin had not lived, are interesting—tending, as they do, to show how indispensable was the work of the great naturalist in focusing the facts and showing the method. Or, to quote a somewhat happy metaphor of his own, "Darwin was not, as most people falsely imagine, the Moses of evolutionism, the prime mover in the biological revolution; he was the Joshua who led the world of thinkers and workers into full fruition of that promised land which earlier investigators had but dimly descried from the Pisgah-top of conjectural speculation."

Almost the only criticisms we have to advance relate to matters of opinion. Thus, for instance, the following passage seems to us absurd:—"Strange to say, the abortive theory [of Pangenesis] appeared some years later than Herbert Spencer's magnificent all-sided conception of 'Physiological Units,' put forth to meet the self-same difficulty. But while Darwin's hypothesis is rudely materialistic, Herbert Spencer's is built up by an acute and subtle analytical perception of all the analogous facts in universal nature. It is a singular instance of a crude and essentially unphilosophic conception endeavouring to replace a finished and delicate philosophical idea." Now we can very well understand any one who has read both the theories including them in the same condemnation, as too highly speculative, devoid of verification, and so forth. But we cannot understand any one thus exalting the one to the disparagement of the other—and least of all so on the ground that Darwin's version is "rudely materialistic." Where can there be room for any other element than the "materialistic" in the case of an hypothesis which has to do with facts purely physiological? The objection to Spencer's version we have always taken to consist precisely in its "acute and subtle perception of all the analogous facts in universal nature," whereby we are gradually translated beyond the world of physiology altogether, until we may exclaim with St. Paul—"Whether I am in the body or out of the body I cannot tell."

And this leads us to a second criticism of a more general nature. Mr. Allen, we think, is too fond of comparing the work of Darwin and Spencer, and when doing so appears to us to attach an altogether undue merit to what he calls the "deductive" as distinguished from the "inductive" method. The work of these two great Englishmen is so unlike that, even though it has been expended upon the same subject-matter, it always seems to us a great mistake to compare them; we might almost as well seek to compare the work of an historian with that of a poet. "What an ex-tra-or-dinary wealth of thought that man has," was once observed to the present writer by Mr. Darwin: "when I first read his 'Principles of Biology' I was speechless with admiration; but on reading it again I felt in almost every chapter—Why, there is here at least ten years' work for verification." Now this is surely a sound judgment, and one, moreover, in no way disparaging to the genius of Mr. Spencer. But if it is a sound judgment, surely also it shows the mistake of comparing his genius with that of the man who wrote the passage more than once quoted by Mr. Allen—"After five years' work I allowed myself to speculate on the subject."

Again, with reference to the relative values in biology of the deductive and inductive methods, Mr. Allen appears to us behind the age. To quote only one passage, he says:—"The English intelligence in particular shows itself as a rule congenitally incapable of appreciating the superior logical certitude of the deductive method. Englishmen will not even believe that the square on the hypotenuse is equal to the squares on the containing sides until they have measured and weighed, as well as they are able by rude experimental devices, a few selected pieces of rudely shaped rectangular paper." Now, it is easy to sustain the doctrine here implicated with examples drawn from Euclid; but biology is not mathematics, and if any one truth more than another is necessarily and forcibly brought home to the intelligence of a biologist—be he "English" or otherwise—it is the truth that in his science it is safer to cut out his materials in the way of experiment, than it is to build up his propositions in the way of deduction. Therefore, it is not without good reason that a proved "soundness" in this way of inductive research should be regarded as the best title to a place among men of science as distinguished from men of letters. "To be sound," says our author, "is everywhere of incalculable value;" and to be sound in the present sense, "to have approved one's self to the slow and cautious intelligence of the Philistine classes, is a mighty spear and shield for a strong man; but in England, and above all in scientific England, it is absolutely indispensable to the thinker who would accomplish any great revolution. Soundness is to the world of science what respectability is to the world of business—the *sine quâ non* for successfully gaining even a hearing from established personages." And long may it continue so. Surely this acknowledgment of the supremacy of the inductive over the deductive methods has been gained by a sufficiently long struggle in the past, and surely the tardiness of this acknowledgment has been fraught with evils sufficiently conspicuous to render somewhat grotesque the term "Philistine classes" as thus applied to the devotees of observation and experiment.

There is only one other passage upon which we have anything resembling a criticism to pass, and we notice it the more readily because, while it relates to a somewhat important matter of fact, the fact is one the unwitting and quite excusable misstatement of which by the present biographer furnishes a good opportunity for rendering its true complexion. In his chapter on "The Period of Incubation of the Origin of Species" Mr. Allen says:—

"His way was to make all sure behind him, to summon up all his facts in irresistible array, and never to set out upon a public progress until he was secure against all possible attacks of the ever-watchful and alert enemy in the rear. Few men would have had strength of mind enough to resist the temptation offered by the publication of the 'Vestiges of Creation,' and the extraordinary success attained by so flabby a presentation of the evolutionary case: Darwin resisted it, and he did wisely. We may, however, take it for granted, I doubt not, that it was the appearance and success of Chambers' invertebrate book which induced Darwin, in 1844 (the year of its publication), to enlarge his short notes 'into a sketch of the conclusions which then seemed to him probable.' This sketch he showed to Dr. (now Sir Joseph) Hooker, no doubt as a precaution to insure his own claim of priority against any future possible competitor. And having thus eased his mind for the moment, he continued to observe, to read, to devour *Transactions*, to collate instances, with indefatigable persistence for fifteen years longer."

Now, we have quoted the whole of this passage because it serves to convey, in clearly expressed language, what is a very general misapprehension with regard to the length of "the incubation period." But Mr. Darwin has himself told the present writer that the reason why he was so long in publishing his theory was simply because he wished to be fully persuaded in his own mind as to its truth before he incurred the moral responsibility of giving it to the world. Most of all those twenty years were occupied in collecting evidence, and in that process of self-criticism which he used to call "meditation," with the single-minded view of self-persuasion. Here was surely a nobler motive, and one more worthy of an "inductive mind," than that of accumulating evidence merely in order to make out a good "case." We doubt whether the popularity of the "Vestiges" exercised the smallest influence upon Mr. Darwin's motives. He had no desire to make a stir merely in order to secure a literary success; and therefore he felt that the more attention his work was likely to attract the more pernicious was it likely to prove, unless it was throughout founded upon truth. Neither was he actuated by any petty regard for priority. The reason why he showed his notes to Dr. Hooker was because he entertained a higher regard both for the learning and the judgment of this friend than he did for those of any other man.

By a curious coincidence Dr. Kraus's biography of Darwin appears in Germany about the same day as Mr. Allen's in England. As we have thus received the two by consecutive posts, it is impossible to avoid comparing them. And the comparison is interesting, as showing the differences between the public tastes to which the biographies are respectively addressed. While the English volume is a pleasing sketch of a great life, the German counterpart is an honest piece of history. Dr. Kraus has spared no pains in making his work thorough. He has carried his investigations through the smallest detail of Mr. Darwin's life and labours; he has brought together a number of letters written by Lyell, Hooker, Haeckel, Müller, &c., and also by Darwin himself; he has given a methodical account of the opinions entertained upon Darwinism by all the naturalists of any note in Europe and America who have either written or spoken upon the subject; and he has done all this without losing sight of the strong personal interest which attaches to the character of the immortal Englishman.

Many of Mr. Darwin's own letters just alluded to are translations of those written to Prof. Henslow during the voyage of H.M.S. *Beagle*, and printed for private circulation among the Fellows of the Philosophical Society of Cambridge. But all the others are translations of letters now printed for the first time—the originals having been lent for this purpose to Dr. Kraus by Haeckel, Preyer, Fritz Müller, and others. These letters are all more or less effective in displaying the distinctive qualities of their author's mind; but if we were requested to indicate one more than another which is of interest in this respect, we should mention the one to Haeckel in which the following passage occurs. The original English is not given:—

"Ich hoffe, dass Sie mich nicht für unverschämt halten werden, wenn ich eine kritische Bemerkung mache: Einige Ihrer Bemerkungen über verschiedene Autoren erscheinen mir zu streng, obwohl ich kein gutes Urteil über diesen Gegenstand habe, da ich ein so kümmerlicher Schulknabe im Deutschlesen bin. Ich habe indessen von verschiedenen ausgezeichneten Autoritäten und Bewunderern Ihres Werkes Klagen über die Härte Ihrer Kritiken vernommen. Dies scheint mir recht unglücklich, denn ich habe seit lange beobachtet, dass grosse Strenge die Leser verführt, die Partei der angegriffenen Person zu ergreifen. Ich kann mich bestimmter Fälle erinnern, in denen Herbigkeit direkt das Gegenteil der beabsichtigten Wirkung hervorbrachte. Mit Sicherheit empfinde ich, dass unser guter Freund Huxley, obgleich er viel Einfluss besitzt, noch weit grösseren haben würde, wenn er gemässigter gewesen und weniger häufig zu Angriffen übergegangen wäre. Da Sie sicherlich eine grosse Rolle in der Wissenschaft spielen werden, so erlauben Sie mir, als älterem Mann, Sie ernstlich zu bitten, über das nachzudenken, was ich zu sagen gewagt habe. Ich weiss, dass es leicht ist zu predigen und scheue mich nicht, zu sagen, dass, wenn ich das Vermögen besässe, mit treffender Schärfe zu schreiben, ich meinen Triumph darin setzen würde, den armen Teufeln das Innere nach aussen zu kehren und ihre ganze Albernheit blosszustellen. Nichtsdestoweniger bin ich überzeugt, dass dies Vermögen nicht gut thut, sondern einzig Schmerz verursacht. Ich möchte hinzufügen, dass es mir, da wir täglich Männer von denselben Voraussetzungen zu entgegengesetzten Schlüssen kommen sehen, als eine zweifelhafte Vorsicht erscheint, zu positiv über irgend einen komplizierten Gegenstand zu sprechen, wie sehr sich auch ein Mensch von der Wahrheit seiner eigenen Schlüsse überzeugt fühlen mag. Und nun, können Sie mir meine Freimütigkeit vergeben? Obgleich wir einander nur ein einziges mal begegnet sind, schreibe ich Ihnen, wie einem alten Freunde, denn das sind meine Empfindungen Ihnen gegenüber."

The chief value of the German biography consists in its setting forth the early recognition, the rapid spread, and the present acceptance of Darwinism in Germany. Dr. Kraus has always an easy case where he is displaying the old truth about a prophet among his own kindred. It was not until after we had well stoned our prophet that the nation began to recognise the reality of his mission; and, as Dr. Kraus remarks, it was not until after we had lost him that England was awakened to the true magnitude of her greatest son. So it was that, Samson-like, he slaughtered his enemies even in his death, and this on a scale which would have astonished no one more than himself, could he have lived to see it.

Dr. Kraus's narrative everywhere glows with an enthusiastic admiration of Mr. Darwin's character, and on this account he deems no trait of thought, expression, or even of movement, too trivial for the purpose of rendering a mind's-eye portrait to his reader. On the whole, this word-painting is accurate, and the workmanship in good taste. As he himself remarks, however, exception may perhaps be taken in the latter respect to his having entered upon the religious opinions of the naturalist. But as he has only collected material upon this subject which had already been published, and as he re-publishes this material in an excellent spirit of toleration towards all varieties of religious belief, we do not ourselves think that he can be justly said to have overstepped the limits of good feeling.

From this brief notice it may be gathered that Dr. Kraus's book is both a thorough and an interesting piece of biographical work; and we must not forget to add that its interest is enhanced by two portraits of Darwin (one, the last that was taken, and the other a likeness of him as a young man), a picture of his house in Kent, and a facsimile of one of his letters.

GEORGE J. ROMANES

OUR BOOK SHELF

British Zoophytes; an Introduction to the Hydroida, Actinozoa, and Polyzoa found in Great Britain, Ireland, and the Channel Islands. By A. S. Pennington, F.L.S. (London: L. Reeve and Co., 1885.)

THE object of this book is to furnish a handy, and at the same time reliable, manual of British zoophytes, using this term in somewhat the same sense as Dr. Landsborough did; and the author aims at making it do for the present generation of students what the reverend doctor's "Popular History of British Zoophytes" did for those of a former one.

In so far as the object of the author has been to furnish a catalogue of the Polyzoa and most of the Cœlenterata of the British Isles, this has been fairly fulfilled, and, as far as we have been able to judge, the catalogue is in most instances a reliable one; but the student will not find it a ready help to the determination of the species; for though in most cases the diagnoses of the genera are given, yet it is but rarely that there is enough of a hint given as to the specific characteristics of a form to enable its name to be even guessed at; so that the working biologist interested in naming the species he collects must still have by him the works of Gosse, Hincks, and Busk. The usefulness of this volume would undoubtedly have been vastly increased if the labour had been gone through of giving analytical tables of both the genera and species, and it seems to us very undesirable that new species should be introduced into a work like this without detailed diagnosis. The size of the volume need not have been greatly increased if a uniform diagnosis of the species had been attempted, for then no doubt would have been curtailed the quotations, often of no scientific value, from the writings of Dalyell and others.

We have also to regret that the list of the habitats seems to us not to have been judiciously selected. Thus, in the case of some of the rarer forms, it is not unusual to find the exact English localities given, but these followed by such indefinite indications as "Irish" or "Scotch" coasts.

In the introductory chapter we find a somewhat ambitious attempt to write the history of the progress made from 1599 to the present time in our knowledge of "zoophytes." We have no wish to be critical on the facts mentioned, but to find the writings of Trembley, Peysonnel, Réaumur, Ellis, and Fabricius quoted, and the name of Esper, emphatically the eighteenth-century authority on this "group," not even alluded to, strikes us as curious.

As long as the author had the writings of Hincks, Busk, or Gosse to depend on, there he has been at his ease; but in the few cases where he has had to go unaided, as among the Alcyonaria, it is evident that he would have been the better for some help. In such instances, as indeed all through his work, he would have found more assistance from "Carus Prodomus Faunæ Mediterraneæ" than from isolated papers in our scientific journals.

The bibliography in Appendix A is quite unworthy of the name. From it alone no student would, without assistance, find out even what the authors wrote about. Fancy bibliographical references in these modern days, and in a work written for the present generation, of this style:—

1742. Réaumur, "Histoire des Insectes."

1821. Deslongchamps, "Encyclopédie Méthodique."

1838. Milne-Edwards, "Recherches sur les Polyps."

1864. Rev. A. M. Norman, "Contributions to 'Ann. of Nat. Hist.,'" &c.

1884. Andrés, "Die Actinien."

In Appendix B—the glossary—many words are given without any explanation of their meaning; thus, while we learn that *aperture* is "an opening or orifice," and that *orifice* is an "opening," that *apex* is "the top of anything," &c., we have such words as the following left unexplained: *avicularia*, *bathymetrical*, *calyx*, *epistome*, *funiculus*, and so on.

It is just on such matters as we criticise that we have a right to expect in a compilation that care should be taken. The general usefulness of such a volume depends on the way in which each detail is worked out. Motives that the reader of the preface will understand make us refrain from any criticism on the plates, save that the figures are for the most part of necessity from the originals in Van Voorst's well-known series.

Handbook of Jamaica, 1885 86. (London: Stanford.)

THIS is one of the most comprehensive books of the kind that has come under our notice. Everything connected with this interesting colony finds a place in it. The history of the island, for instance, and the geographical description of it might be read with advantage by the most general reader. Of special interest to scientific readers is the full account of the public gardens and plantations, now under the efficient control of Mr. Morris, whose reports we have noticed from time to time as they were published. In the "Handbook," however, a history of the department since 1774 is given; and it is curious to notice the influence it has had on the prosperity of the island. Except pimento, "that child of nature," and a few others of comparatively little value, most of the staple products of Jamaica are derived from exotics or plants introduced from other parts of the globe. Thus the sugar-cane, in its several varieties, coffee, the mango, logwood, cinnamon, the bamboo, mulberry, mimosa, camphor, clove and pepper plants, and many other products of great commercial importance to the island, were unknown a century and a half ago. The manner in which they were brought in is given from historical sources. Thus, that most important industry, cinchona-planting, was only introduced in 1861, on the recommendation of the late Sir William Hooker; the first seeds were planted in the Botanic Gardens, and the first plants reared and distributed from there. In 1884 73,533 lbs. of cinchona bark, valued at 16,327*l.*, were exported from Jamaica. Many other examples of the great economical benefits of these Botanic Gardens on Jamaica might be selected from the interesting historical account of them given in this handbook. The sketch of the Jamaica Institute is also of much interest.

Syllabus of a Course of Lectures on Physiology, delivered at Guy's Hospital. By Dr. P. H. Pye-Smith. (London: J. and A. Churchill, 1885.)

THIS volume consists of the outlines of lectures given from time to time by the author at Guy's. The author, in publishing it, aims at giving the student a help to systematic reading and self-examination, as also to recall to all who take an interest in physiology, the chief facts of this important subject.

Consisting, as it does, of the heads and indications of subjects, this work is one that naturally cannot, in the ordinary sense of the term, be read through, nor will it serve in any way to cram a student for an examination: but we have kept it by us, and from time to time returned to its pages with ever-increasing interest. Though long past the period of life usually described as the "student stage," the ideas presented to us in this book, whether concerning facts, theories, or the deeply-interesting history of the subject, have compelled us to become students again, and we feel it a duty to urge our younger brethren, who are engaged in their first studies of physiology, to consult this little volume, as it is meant to be consulted; and if there be in them the smallest measure of an aspiration for a knowledge of a science as important as it is fascinating; if they be earnest, honest students, they will thank us for calling their attention to a volume which, in a small space, compasses so vast a subject.

Nature and Her Servants; or, Sketches of the Animal Kingdom. By Theodore Wood. (London: Society for Promoting Christian Knowledge, 1886.)

THIS is a well-intentioned little work, illustrated by a set of, for the most part, unobjectionable woodcuts. It is intended for the young, and so scientific terms have been almost wholly discarded. The author states very correctly, that in order to impress a fact upon the mind of a child, that fact must be presented in an interesting and attractive manner, and it is presumably bearing this in mind that he has selected the title to his volume, for children soon learn to know all that is attractive and interesting in the conception of a servant, and the child that reads the introductory chapter to these sketches of the animal kingdom will have this subject brought before him in full detail. But as the thinking child reads on, will his tender mind not be frightened at the notion so forcibly dwelt upon by Mr. Wood, that this serving Nature means that the strong servants should kill and swallow the weak; that while by one law of "Mistress Nature" the servants are to increase and multiply, by another law of the same Dame the feeble and the little ones are destroyed by the strong and the big, and that it is thus that these servants, now become foes, "fulfil their trust." The young inquirer who reads this on the first page may find it hard to agree with the statement on the last page, that "Nature is a good mistress, and provides her servants with all that they may require."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Whole Duty of a Chemist

I HAVE read with much interest your article on "The Whole Duty of a Chemist." To me it appears perfectly clear that he who does good work in professional science and is paid highly for it, is accorded less honour than he who does equally good work in original scientific research and receives no personal payment, because the former receives a pecuniary reward for his labour whilst the latter does not; the least honour is given where there is the least self-sacrifice. The man who does original research with the ultimate object of securing remunerative scientific employment, works with a less unselfish motive and object than he who does such research from a pure love of truth and a desire to benefit mankind. But whilst the pursuit of new knowledge has always been considered a nobler occupation than the pursuit of money, most scientific investigators do some remunerative work, and workers in both departments are necessary for the general welfare. G. GORE

Institute of Scientific Research, Birmingham

The Recent Star-Shower

LA pluie extraordinaire des étoiles filantes du 27 Novembre, 1872, s'est renouvelée cette année le même jour et à peu près avec la même intensité. D'après les télégrammes et les rélations que nous avons reçus en grand nombre jusqu'à présent, il résulte que le phénomène en question a été remarqué dans toute l'Italie depuis les Alpes jusqu'à l'extrémité de la Sicile, et qu'il se produisit partout sous les mêmes formes. Il commença à la tombée du jour. A Tarente, à 5 heures du soir, les étoiles jaillissaient et filaient en lignes si compactes qu'elles perçaient de temps en temps l'obscurité déjà avancée de la nuit. A Palerme quelques-uns de nos anciens élèves ingénieurs comptèrent 4600 météores de 5h. 15m. à 6h. 30m. A cette heure la pluie météorique se manifestait en plusieurs autres endroits avec une abondance tout à fait surprenante.

Dans notre Observatoire on commença à explorer le ciel à 6h. du soir (temps moyen de Rome). Nous avons suivi la même méthode que je suivis in 1872; les observations actuelles peuvent en conséquence étre comparables avec celles d'alors. Comme j'eus déjà plusieurs fois l'occasion d'exposer cette méthode je crois à propos de l'omettre ici. Je me bornerai à rapporter les résultats obtenus de 15 en 15 minutes; et âfin de mieux éclaircir ma rélation, je vais donner ci-dessous un tableau dont la seconde colonne indique le nombre des observateurs chaque quart d'heure ; et la troisième l'état de l'atmosphère en dixièmes de ciel libre. La quatrième colonne contient le nombre des météores réellement comptés, et la dernière le nombre supputé des étoiles, c.á.d., le nombre qu'on aurait dû avoir par conjecture si les observateurs eussent été toujours au nombre de quartre et que le ciel eût été toujours serein.

Durée de l'observation	Nombre des observateurs	Dixièmes de ciel découvé	Nombre des météores	
			Observés	Calculés
6.0 — 6.15	2	10	2800	5600
6.15— 6.30	2	10	3400	6200
6.30— 6.45	$2\frac{1}{5}$	10	3400	6200
6.45— 7.0	3	10	4500	6000
7.0 — 7.15	4	10	6200	6200
7.15— 7.30	4	7	3500	5000
7.30— 7.45	$3\frac{1}{2}$	7	3100	4900
7.45— 8.0	4	7	3200	4600
8.0 — 8.15	4	7	3100	4400
8.15— 8.30	4	7	1700	2400
8.30— 8.45	4	6	1500	2500
8.45— 9.0	4	5	1000	2000
9.0 — 9.15	4	5	800	1600
9.15— 9.30	4	4	600	1500
9.30— 9.45	4	4	500	1200
9.45—10.0	3	3	234	1000
10.0 —10.8	4	3	312	1000
Heures 4.8	—	—	39,546	623,000

Le ciel fut obscurci à 10h. 8m. par un épais brouillard, qui le déroba à nos yeux tout le reste de la nuit. Ailleurs aussi de noires vapeurs voilèrent le ciel à la même heure et même avant. Seulement dans quelques localités de montagne et du midi où le ciel se conserva serein jusqu'à l'heure la plus reculée de la nuit on affirma d'un commun accord qu'à 11 heures le phénomène était presque fini. Les observations que nous avons faites dans les deux soirées suivantes du 28 et du 29 nous conduisirent à un résultat identique.

En 1872 nous en vûmes 33,000 dans l'espace de six heures ; cette fois-ci, quoique les observateurs ne fussent pas toujours au nombre de quatre comme à cette époque, nous en avons compté 39,000.

En 1872 l'abondance des étoiles atteignit son maximum entre 7h. 45m. et 8h. 45m. ; cette année au contraire le maximum avait eu déjà son commencement, quand le phénomène prit à paraître, ainsi que le prouvent les nombres calculés à Moncalieri dans les deux premières heures, lesquels sont presque constants. Beaucoup ont assuré que dès la nuit du 26 au 27 on vit une grande foule des météores sillonner les airs ; ici le ciel était chargé. Les observations des régions orientales répandront plus de lumière sur ce sujet.

En 1872 nous étions toujours au nombre de quatre observateurs et nous comptâmes 18,600 étoiles filantes pendant les deux heures proches du maximum, tandis que cette fois-ci, dans le même temps et presque toujours au nombre de deux ou de trois, nous sommes parvenus à la chiffre imposante de 29,800. Nous nous hâtons cependant de dire que toutes ces chiffres ne donnent qu'une estimation approximative de l'apparition, puisque pendant ces deux heures on ne comptait guère chaque météore, mais les groupes des étoiles seulement (et pas même tous), qui se succédaient presque sans interruption.

Par conséquent les résultats obtenus dans ce temps ne représentent que la cinquième ou la sixième partie et peut-être sont-ils inférieurs au réel.

Je crois donc ne pas m'abuser en assurant que le nombre des étoiles apparues dans le temps de nos observations n'a pas été au-dessous de 150 à 160 milles. Le spectacle qui s'offrit à nos yeux pendant les deux premières heures du maximum était surprenant, et tel qu'on trouverait de la peine à la décrire. De toutes les parties du ciel il pleuvait des masses d'étoiles semblables à des nuages cosmiques qui ce fondaient. Elles étaient suivies de traces lumineuses, et beaucoup de ces étoiles surpassaient celles de première grandeur ; quelques-unes même étaient de véritables bolides. La marche était, en général, lente, et la couleur prédominante était le rouge tant à Moncalieri qu'ailleurs occasionnée par les nombreuses vapeurs éparses dans l'atmosphère. Les méteores qui se trouvaient le plus près des régions irradiantes étaient très courts : aussi plusieurs n'étaient-ils que des points flamboyants par lois de prospective.

La plus grande partie jaillissait de la région même dont elles irradiaient en 1872, et laquelle se trouve entre Persée, Cassiopée, et Andromède. On ne distinguait aucun centre sécondaire comme dans les soirées ordinaires de la plus grande affluence.

Je mis tous mes soins à déterminer exclusivement la position du radiant, ce qui ne présentait aucune difficulté. Voilà de quelle manière je m'y pris. Je fixai attentivement sa position approximative, et ensuite je traçai sur le papier le chemin de quelques-uns de ces météores qui se détachaient autour de ce point. J'achevai de cette façon presque 190 trajectoires, dont chacune à son tour en représente une infinité d'autres, qui suivaient le même chemin. En partageant ces trajectoires en trois groupes, j'ai obtenu les trois positions suivantes :—

	h. m.		Radiant
A	7 35	... ...	$\alpha = 22°, \delta = +44°$
,,	8 20	... ...	$\alpha = 26, \delta = +43$
,,	9 8	... ...	$\alpha = 28, \delta = +42$

Ces points sont compris entre ϕ et γ d'Andromède et le troisième point est tout près de cette dernière étoile.

Mon savant collègue, M. Schiaparelli, eut pour résultat :—

	h. m.		Radiant
A	6 35	... ...	$\alpha = 15°, \delta = +45°$
,,	7 12	... ...	$\alpha = 18{\cdot}5, \delta = +44$
,,	8 7	... ...	$\alpha = 23, \delta = +42$

En conclusion, la grande quantité de météores observés de ces jours est la même que l'on vit en 1859 et en 1872 ; elle se présente avec un interval le de 13 ans qui correspond à la double période de la comète de Biela-Gambart, avec laquelle cet essaim météorique a des rélations immédiates.

P. J. DENZA

De l'Observatoire de Moncalieri, 30 Novembre

ON the night of November 27, when off the Straits of Gibraltar, time 6 p.m. (6.45 G.M. time), weather fine and clear, sky cloudless, I witnessed what must be of rare occurrence in high northern latitudes—a fine meteoric display, unsurpassed by anything of the kind I had the good fortune of seeing before.

From a point in the heavens situated about the Elliptical Nebula (31 M) in Andromeda radiated in all directions towards the horizon, an immense number of meteors, numbering, as far as I could count, about 30 per second from 6th mag. to beyond the apparent magnitude of Venus, as best seen, the greater number of which were apparently of the 2nd to 4th mag. and plainly visible through a space of 40°, travelling, as far as I could judge, about 10° per second.

This display continued without intermission to about 10.30 p.m., when the light of the rising moon put an end to its brilliancy, though the larger meteors still continued to be seen throughout the night.

I noticed one large meteor in particular, far surpassing Venus in magnitude and splendour, burst forth from a spot about 10° south-west of Markab, and, after traversing a space of 60° in a south-westerly direction, suddenly disappear, leaving behind it a long train of bluish-white light, which after the disappearance of the meteor began to assume different forms. The lower part of the line recurved on its path, travelling to the south-east, east, and north, until it finally joined the upper line, forming an elongated ellipse which appeared plainly to the naked eye for the space of 15 minutes. It had the appearance, when viewed through a pair of binoculars, of a light white cloud that the moon is just illuminating, and in its passage across A and V Aquarius (as the body of it still held a northerly direction) it made them to appear as if light steam was passing across them. It finally disappeared like round nebula to assisted sight after being seen for over 25 minutes.

The whole display might be likened to a huge umbrella, 31 M, the radiating point being taken for the point or apex and the shooting-stars the ribs.

The most brilliant and largest meteors held invariably a south-easterly to south-westerly direction, and the radiating-point was situated during the display from 30° east to 30° west of the zenith. JOHN M'KEAGUE

s.s. *Acadia*, December 3

A MAGNIFICENT meteoric shower was visible here on November 27, from soon after sunset till the sky was clouded over at midnight. The maximum appears to have been between 8 and 9 o'clock.

At 6h. 30m. two observers watching opposite parts of the sky counted 850 meteors in 5 minutes. At 7h. 50m. (5h. 30m. Greenwich mean time) seven observers divided the heavens among them and together counted 525 in one minute. We all agreed that we had not been able to count all that we saw, so that this number is probably too small. At any rate I do not think the number of meteors visible between 7 and 9 p.m. was at any time less than 500 per minute. At 10h. I alone counted 210 in two minutes, facing the north, which was then partially clouded.

The majority were small, though quite a number were estimated as brighter than Venus. Nearly all had trails, usually bluish-white, but frequently reddish in the case of the larger ones. At no time did I see a trail remain visible more than three seconds after the disappearance of the meteor; some friends saw one which remained visible about five minutes, changing its shape a number of times and gradually vanishing.

I determined the radiant-point carefully by tracing back the paths of a great many. I place it 2° or 3° north-west of γ Andromedæ, R.A. 25° or 26°, $\delta + 43°$ or $+ 44°$. And three times during the evening I saw meteors appear at this point, grow brighter, and die away at the same place, as though coming directly towards the observer. ROBERT H. WEST

Syrian Protestant College, Beyrout, Syria, November 30

I CAN quite confirm what Dr. Main says about the display of meteors being finer in this neighbourhood than seems generally to have been the case, as far as the accounts which I have seen enable me to judge. My attention was not called to the falling-stars until the display was past its best; but at about 7.30 p.m. I held my opera-glass steadily on one spot, and, watch in hand, counted the numbers which crossed the field of the glass, and, repeating this two or three times, I found that more than one per second crossed the field. The exact figures were eleven each ten seconds.

I hastily set up a Coulomb's torsion electrometer, and found the air highly charged with electricity, which may possibly not be without interest in considering the auroral displays mentioned in NATURE. ARTHUR WM. WATERS

Davos Dörfli, Switzerland

THE Bielid meteors were observed here last evening (November 27) in considerable numbers. I had been closely occupied during the day, and had quite forgotten that they were due, so that I did not look out for them immediately after dark, and probably missed the maximum of the shower. On going out of the house at 7.15 (Eastern Standard Time, 5h. later than Greenwich) my attention was at once attracted by seeing two meteors in the sky together, quickly followed by others. In walking about 100 yards I counted 12, and in 10 minutes 36. Up to 7.45 about 100 were recorded in all; in the next 15 minutes only 3 or 4 appeared, and at 8 o'clock I discontinued the observations. Five or six were of the 1st magnitude; about half of the whole number were of the 2nd or 3rd, and the rest of them were mostly very small. The colour, both of the meteors and of their trains, was always *reddish*—never greenish like that of the Leonids. The tracks were generally short, in very few cases exceeding 20°, and the motion was rather slow. The position of the radiant, determined largely by three nearly stationary meteors, but agreeing also with results obtained by plotting other meteor paths, was about 2° north-west from γ Andromedæ:—α, 1h. 50m.; δ, 43°·5. The radiant was not a point but rather a region about 4° long north and south, and 2° wide. C. A. YOUNG

Princeton, N.J., U.S.A., November 28

THE meteors were seen here till 7h. 10m., when the sky became overcast. They were first noticed before it was dark, as early as 4h. 35m. and they were then abundant, though smaller ones must have been hidden by the twilight. Although cloudless, the night was not favourable, and below an altitude of 45° there was much haze, so as to sensibly dim meteors that descended below this altitude.

Scarcely any of the meteors had an apparent nucleus. Nearly all appeared as sparks, and at first scarcely increased in size, at last suddenly blazing out into a considerable number of sparks, and then almost immediately disappearing, and there was an absence of the usual lingering streaks. The meteors were remarkably abundant, especially before 6 p.m. At 5h. 25m., facing south-east, I counted 21 in ten seconds, whilst a gentleman facing north-west counted 17. The number seen between 5 p.m. and 6 p.m. must have been at least 100 per minute. Though the meteors were almost constant, they were spasmodic as regards numbers, for every few minutes suddenly the air seemed full of them. Very few were erratic, and the stream going in one direction was a conspicuous feature. Meteors passing over the same path were alike as regards the length of their paths, with this qualification: the smaller ones were invisible sooner than those of larger size.

The average size of the larger ones was not great, yet early in the evening they were larger than those seen in 1872. The largest was seen exactly at 5h. 30m.; this passed close to α Andromedæ, and it was about equal to the apparent size of Venus.

Near the point of convergence, not far from γ Andromedæ, the paths were very short, and on the point itself there were no less than five that blazed out and died away without moving, three were mere points, and two were equal to Sirius in apparent size; they also disappeared at their maximum brightness, but did not separate into sparks.

There was evidently a second point of convergence near η Cassiopeiæ, and these meteors were not as brilliant as those converging to γ Andromedæ; no stationary ones were, however, noticed here.

The general colour was that of ordinary gas, a few only being intensely blue. Those nearer the horizon had a red look, but this was owing to the haze, for their colour only changed when passing into this haze.

In 1872 one meteor—a mere spark—I saw between me and a hill (80 feet elevation), and again to-night two others passed between me and a hill. These must have fallen to the ground. They were moving almost horizontally.

The display this evening, both as regards numbers and general appearance, was very similar to that of 1872

Shirenewton Hall, Chepstow, November 27 E. J. LOWE

P.S.—Owing to work in connection with the General Election this report was unfortunately not posted on the 28th. The 28th was unusually clear, with an absence of clouds; but from 8 p.m. till 9 p.m. I only noticed two meteors, and they came from the direction of Cassiopeia.

THE expected meteoric shower was seen here between 8 and 8.30 on the evening of November 27. The weather was misty and the sky partly overcast.

The stars fell in great numbers from an invisible (owing to cloud obscuration) radiant-point in or near Andromeda, and with a slow motion, their movement being more like that of large flakes of snow falling gently through the air than that of shooting-stars. Numbers fell, apparently perpendicularly; the greater part, however, took a southerly and south-westerly direction, very few taking an eastern and north-east course. The display was intermittent, occasionally nearly ceasing, and then showering in great numbers, which it was found impossible to count. About 8.30 p.m. the sky was completely overcast, and drizzly rain was falling.

The meteors were of uniform size and of the same colour—a bright whitish-yellow. A few of larger size were seen, and these were somewhat darker and their flight more prolonged.

WM. H. LYNE

British Cemetery, Scutari, Constantinople

WITH reference to Mr. Haslam's remarks (NATURE, December 10, p. 128) as to the coincidence of auroræ with star-showers, I believe that their combined apparitions have no meaning further than that resulting from pure accident. I have seen many rich star-showers without the faintest visible trace of auroral manifestation, and many bright displays of auroræ have been watched here without indication of an associated star-shower. Still, the circumstance that certain meteoric displays have occurred contemporaneously with other phenomena, is interesting (though not, perhaps, significant, as intimating any physical connection), and such records should always be preserved, as possibly having a value which further observations may elucidate.

During the great meteoric shower of November 13, 1866, several observers detected a faint diffused light of an auroral character in the northern sky.

In 1880 there were bright displays of auroræ on August 11, 12, and 13. Whilst watching the Perseid meteor-shower on those nights, I noticed the successive appearances of streamers and light condensations in the northern quadrant. On the 13th the sky was much lighter than usual, though no streamers or bright glows were visible. The moon set before 10h., yet at midnight the air was not dark; objects around were discernible with remarkable facility beneath the luminous gauze of the aurora apparently diffused over the sky.

During the present month I have been engaged in a series of observations of the Geminid meteor-shower. On December 7, 8, 9, and 10, I especially noticed singular light-radiations, like broad films of faint white cloud, in the northern region. These were very striking on December 9, and persistent during several hours. The most conspicuous of these radiations stretched out of the horizon in the north-north-east, and ran obliquely a considerable distance east, where it enveloped the stars of Virgo and Leo. The effect was somewhat similar to that of the zodiacal light, but in the present case the phenomenon had an evident tendency to remain in the vicinity of the horizon. On its upper side I distinguished very faint indications of streamers, with alternating spaces rendered very dark by contrast. The appearances were, however, so constant, that they can hardly be associated with the characteristic mobile forms of ordinary auroræ. The sky generally was very light, and I have specially noticed this fact on several other occasions this month, when an observer might readily have assumed that the moon, in one of her quarters, was present in the firmament.

A suffused glowing of the whole sky such as that now recorded has not infrequently been visible here in past years during the progress of meteoric observations. Though no definite auroræ (in its normal features) can be descried, there is obviously some modification often present imparting to the firmament those peculiarities of aspect and tint which are far too striking to escape notice. I believe that scarcely a very clear night passes but there may be traced, with a critical eye, some feeble traces of auroræ, or their closely-allied phenomena. Could these ever-varying sky-tints be studied in a fine climate, I feel assured we might look for some interesting results.

Bristol, December 12 W. F. DENNING

The Supposed Fall of an Aërolite in Naples

THE late beautiful meteoric display, which was well seen here, has given rise to a somewhat ludicrous incident. The local papers on Sunday evening and Monday contained an account of an aërolite that had fallen in the Strada Fiorentino, one of the principal thoroughfares of the town; that this stone weighed between 6 and 7 kilogrammes, and had nearly struck some people who were passing. This announcement was followed by a description of the stone from the pen of one of the professors in the University, together with an account of meteorites in general.

Such a display of erudition, coinciding with the bombardment our earth has had from Biela's comet, prevented my sleeping all night, and, as early as etiquette would allow, I paid a visit to the house of the two professors, the *happy* (?) possessors of this would-be aërolite. The first examination convinced me that we had to deal with a shoemaker's lapstone of Vesuvian lava, the patina being nothing more than the polish of grease, dirt, with wear and tear. A small fragment was given me, which, after being sectionised, showed a typical leucitophyre of Vesuvius—probably the lava of 1631 from "La Scala" quarries.

I should not have written to you had it not been that such confirmation had been given by men of position, whom I have now obliged to admit their mistake. Probably, however, the report of the fall of this supposed aërolite has already spread, so that I fear it may be included in lists of historic meteorites.

I may say that the stone had probably fallen or been thrown from one of the roofs of the neighbouring high houses.

The Rotation-Period of Mars

IN the number of NATURE of November 26 (p. 81), Mr. Proctor mentions one or two points in my investigation of the rotation-period of Mars, requiring correction.

The first is, that I did not use Proctor's final result for the period, but one which he published in 1869, differing 0·02s. from the former. As I intended to determine from the whole series of Mars's drawings the correction of the rotation-period, it was perfectly indifferent what value I adopted in my calculations; the only condition was, the error should not be so great as to cause an erroneous interpretation of the Mars pictures of former years. A difference of 0·02s. in the adopted rotation-period changes the position of the markings in the drawings of Huygens and Hook but 2°·9, so that for my purpose I could adopt Proctor's value of 1869 as well as that of 1873. I chose the former, as it seemed, after a preliminary reduction of Schrœter's observations, to be nearer the truth; but my results would have been absolutely the same had I chosen the second.

The second remark of Mr. Proctor's is the following:—"Prof. Backhuyzen, like Mr. Denning some time since, has taken Kaiser's result uncorrected for the clerical errors—very seriously affecting it—which I detected in 1873." As I have used only Kaiser's *original observations*, and no *result whatever, corrected or uncorrected*, I must conclude that Mr. Proctor has not read my paper very accurately; when he does so, he will see that he is wrong. At the same time he can see that on p. 58 the time of Hook's observations is given, "March 12, 12h. 20m. and 12h. 30m.," and from the indication on p. 55, that there is an integral number of revolution-periods of 24h. 37m. 22·74s. between 1862, November 1, 9h. 55m. mean time Berlin, and 1672, January 1, 22h. 11·0m. mean time Paris, he may conclude, after a slight calculation, that I did not count the years 1700 and 1800 as leap-years. My results are, therefore, free from the errors Mr. Proctor indicated; I hope I made no other.

It seems, however, very difficult to avoid them wholly. Mr. Proctor, for instance, who occupied himself so much with the subject, writes, in the above-mentioned number of NATURE of November 26: "Kaiser counts three days too many in comparing Hook's observation with his own: one day, through a mistake in correcting for change of style and two days (apparently) from counting the years 1700 and 1800 as leap-years." That number of *three* days must be *one* day, for Kaiser indicated as the time of Hook's observations, March 13, 12h. 20m. new style, instead of March 12; by this error the number of days from 1862, November 1, till Hook was one day too small; but, by counting 1700 and 1800 as leap-years, Kaiser added two days too many, so that the total error was one day, and not three. Mr. Proctor's conclusions, based on the latter assumption, are naturally erroneous.

Leyden Observatory, December 9

Ventilation

IN NATURE for December 10 (p. 132) I note the suggestion:—"In all new buildings where efficient ventilation is desired, it would be preferable to construct a shaft at one side of, or surrounding the chimney-flue, with an inlet near the ceiling of the room, and the outlet at the level of the chimney-top, so that the air escaping from the room would have its temperature kept up by contact with the chimney, thus aiding the up-draught, whilst the risk of reflux of smoke would be avoided." In building my own house some eight years ago this system was adopted in every room, the outlet over the chandelier being carried across to the side of the chimney of the same room, the two flues being carried up side by side to the chimney stack, each outlet having its own cowl. In practice this has proved a total failure, from the simple fact that the fire-flue is both longer, owing to its starting at a lower level, and that it is also hotter than the other. In the absence of any fire there is a strong upward current in both, but the instant the fire is lighted the upward current in the ceiling ventilator stops, and in a few minutes is reversed, the cold air and collected smoke from the chimney outlet coming in with such force that we have been compelled to make up every ceiling ventilator in the house except one, which, although useless when a fire is lighted, is not a nuisance. Many other experiments in automatic ventilation were tried, so that in case one system failed others might be available, and I regret to say that the only useful remnant of the experiment is the ventilation from the entrance hall, which apparently penetrates with good effect into every room in the house; unfortunately the flue in the entrance hall is one which has a persistent down draught, and we are unable to warm the air in the hall and passages.

There appears to be no rule without exception for automatic ventilation; in one room we have Tobin's ventilators, the opening on the outside facing direct north; these have to be closed always when the room is occupied, as the cold air, after rising a short distance, descends on the heads of the occupants. In another room are four similar shafts built in the wall, the bottom inlets facing west; these shafts are always left full open in the severest weather, the draught being usually downwards and outwards; but why this occurs I cannot form the remotest conception, unless eddies are caused by an adjoining building. There is no doubt that external conditions affect the practical ventilation of any building, and no absolute rules are applicable in every case alike. THOS. FLETCHER

Warrington

Rain at Smyrna

THE telegraph has informed us of a heavy fall of rain at Smyrna on Wednesday, November 25, but few particulars have yet reached us, except some from Capt. Stabb, Corr. Mem. Soc. of Arts. The storm began at six in the morning, and in a few hours 6 inches were registered. When the quay, or embankment, was proposed some years ago, in conjunction with the Council of Public Works I endeavoured to provide an efficient outfall sewer underneath it, but we were defeated by local intrigue. The drainage of Smyrna is worse than in the time of Strabo, by the large additions taken in from the shelving bay. The torrents pouring down from Mount Pagus (the Castle Hill) came through the Turkish quarter, causing the fall of some twenty houses, and washing bodies out of the Turkish and Jewish graveyards. On reaching the lower streets the sewers ceased to act, and cellars, stores, and warehouses were flooded, causing a loss of 50,000*l.* worth of opium, cotton, valonia, and other merchandise, and much damage to private houses. The River Meles overflowed its shallow bed, and reached the Point Railway Station, destroying some market gardens. In the suburb of Bournabat two houses were brought down, and the Cassuba railway embankment was damaged. The storm seems not to have reached beyond Manisa (Magnesia ad Sipylum), over Mount Sipylus, on one side, and Turbalu, beyond the Smyrna plain, on the other. No such inundation has taken place within memory. HYDE CLARKE

The Sea-Mills at Argostoli

WITH reference to the inquiry of your correspondent, Surgeon Lloyd Thomas, in your issue of the 10th instant (p. 129), there is a short paper on this subject by Capt. H. P. Shilston, entitled "On Curious Natural Phenomena in Cephalonia," to be found in the *Transactions* of the Liverpool Geological Association, vol. i. (Liverpool: Henry Young, 1881). The writer describes the inflow of water to the land through crevices in the limestone, as observed by him, and gives an explanation by Prof. Ansted, M.A., F.R.S., who considers that the phenomenon arises from the large amount of evaporation, within range of the district, by which the level of the subterranean stores of water is kept constantly below the level of the sea, notwithstanding the joint supply of rain- and sea-water. O. W. J.

Liverpool, December 12

IN answer to the question of Mr. J. Lloyd Thomas in the last number of your valuable paper (p. 129) respecting the sea-mills of Argostoli, we beg to inform you that we have published, "Die Insel Kephalonia und die Meermühlen von Argostoli, Versuch einer Lösung dieses geophysikalischen Räthsels," von Prof. K. W. M. Wiebel, mit 1 Karte, 3 Skizzen und 5 Holzschnitten, 1873.

Hamburg, December 12 L. FRIEDERICHSEN AND CO.

Friction and Molecular Structure

I SHALL feel obliged if you will kindly allow me to ask any reader of NATURE whether moderate friction can so change the molecular structure of glass as to account for the following fact:—Last night, about twenty minutes after a paraffine lamp had been lighted and had been burning steadily, its glass chimney suddenly burst into small fragments at the exact place at which, about an hour before, I had rubbed it with a piece of brown paper in order to remove soot from the interior. The chimney was thoroughly annealed, having been in constant use for more than three years. The flame was not high; the night was not frosty; the glass was uniformly thin at the place of fracture, which was six inches above the top of the flame, and two inches below the top of the chimney. The part which had not been rubbed is quite uninjured: not even a crack extending into it, while the rubbed part is shattered. EDWARD GEOGHEGAN

Bardsea, December 1

The Resting Position of Oysters—A Correction

MR. J. T. CUNNINGHAM in his letter of November 28 (p. 129), after showing that *Pecten opercularis* must rest on its right valve, goes on to say:—Of *Pecten maximus* I cannot speak with certainty, and therefore leave to Mr. Arthur Hunt the responsibility of stating that there is a difference in respect of position in the two species." So far from my having hinted that any species of Pecten rests on other than the right valve, my letter, to which Mr. Cunningham refers, concludes with the plain statement, "in each case the mollusk rests on the same valve." The point to be noticed is that in *Pecten maximus* the right valve is most convex, and in *Pecten opercularis* the left valve.

A. R. HUNT

Radiolaria

I HAVE recently had the pleasure of finding, in the London Clay, a number of well-preserved specimens representative of several species of Radiolaria, most of which, I have good reason for thinking, differ from any known fossil or recent forms. It was my intention to submit them to the Geological Society during the present month, but circumstances prevent this being done. The delay may lead to an extension of the list, especially if I am fortunate enough to meet with a microscopist kind enough to assist in the examination of material yet untouched. W. H. SHRUBSOLE

Sheerness-on-Sea, December 14

THE CONTINUITY OF THE GERM-PLASMA CONSIDERED AS THE BASIS OF A THEORY OF HEREDITY [1]

THE thoughts developed in this most interesting and important essay were first expressed in a lecture delivered to students of the University of Jena last winter. They were reduced to writing in the spring, and completed for publication in June. The author received Oscar Hertwig's essay on the "Theory of Inheritance," and Kölliker's "On the importance of the Cell-nuclei for the Processes of Heredity," after his manuscript was complete. In the matter of the extreme importance of the nucleus he agrees with both these authors.

As was stated in reviewing here two years ago Prof. Weismann's memoir "On the Origin of the Sexual Cells of the Hydromedusæ," all his memoirs abound in original views and suggestions, which render them of peculiar and widely-spread interest. The present is no exception to the rule. It is intended in this article to give a kind of abstract of the memoir, composed largely of a series of translated passages: for the fuller development of details, the history of the development of ideas on the subject, and controversial matters, readers are referred to the original, which is an octavo of 122 pages.

"How is it," asks the author in commencement, "that in the case of all higher animals and plants, a single cell is able to separate itself from amongst the millions of most various kinds of which an organism is composed, and by division and complicated differentiation to reconstruct a new individual with marvellous likeness, unchanged in many cases even throughout whole geological periods?" The question is a hard one indeed, and the various attempts which have been made to solve it,

1 "Die Continuität des Keimplasma's als Grundlage einer Theorie der Vererbung." Von Dr. August Weismann, Professor in Freiburg i. B. (Jena: Verlag von Gustav Fischer, 1885.)

though most useful as temporary advancements of speculation on the problem, such pre-eminently as Darwin's theory of pangenesis have failed hitherto to dispose of it satisfactorily. It is impossible now to believe that every cell of the organism can give off gemmules which exist at all times in all regions of the body, become collected in the generative cells, and are capable of becoming metamorphosed in regular order back again into the different cells of the organism.

The problem must be considered anew, and the present essay deals not with the entire subject of heredity, but with the fundamental question, How is it that a single cell of the body unites within itself the entire tendencies of inheritance of the whole organism? There are only two physiologically conceivable possibilities by which germ-cells endowed with such peculiar powers as we know them to possess can be produced. Either the substance of the parent germ-cell after passing through a cycle of changes required for the construction of a new individual possesses the capability of producing anew identical germ cells, or *the germ-cells arise as far as their essential and characteristic substance is concerned, not at all out of the body of the individual, but direct from the parent germ-cell.*

It is this latter view which Prof. Weismann holds to be correct, and maintains in the present essay, and which he terms the theory of the continuity of the Germ-plasma. On this theory heredity depends on the fact that a substance of peculiar chemical and even more special molecular composition passes over from one generation to another. This is the "germ-plasma," the power of which to develope to a complicated organism depends on the extraordinary complication of its minutest structure. At every Ontogenesis a portion of the specific germ-plasma which the parent egg cell contains is not used up in producing the offspring, but is reserved unchanged to produce the germ-cells of the following generation.

It is plain that this supposition reduces the question of heredity to one of growth. The germ-cells of all succeeding generations being merely pieces of the same substance as the first, and of the same molecular structure, when nourished under similar conditions, must run through a similar series of stages of development, and yield the same final products.

After combating objections which may be raised to the theory on the score of the heredity of "acquired modifications," it is pointed out that the germ-cells on it appear no longer as a product of the body, at least as far as their essential part, the germ-plasm, is concerned; they are rather to be regarded as something standing opposed to and separate from the entirety of cells composing the body, and the germ-cells of succeeding generations are related to one another as are a series of generations of unicellular organisms derived from one another by a continuous course of simple division into two.

Jäger's and M. Nussbaum's views approached very near those of Weismann; but these authors inferred a continuity of the germ-cells themselves. Such a continuity of cells survives at present in but very few cases. In nearly all instances the generations of germ cells start from the parent, as very minute particles of germ-plasma only, to form, nevertheless, the basis of the germ cells of the next generation.

The author claims for his theory that even should it require to be abandoned in the future, it nevertheless represents a stage in our knowledge of the problem which must be passed through, which must be clearly stated and carefully worked out, whether the future prove it true or false. With this view of it he develops it in three chapters, the first of which deals with the conception of the germ-plasma.

THE GERM-PLASMA.—It now seems established that the only actual carrier of the tendency of heredity is the highly organised nuclear substance; fecundation consists in a union of nuclei; the surrounding cell substance has no immediate participation in the result. E. van Beneden's splendid researches on Ascaris led far towards this conclusion in showing that the nucleus of the egg cell does not fuse in any irregular manner with that of the sperm cell, but that the nuclear loops of these two bodies arrange themselves opposite one another in regular order, two and two, and thus construct the new nucleus, the segmentation nucleus. Van Beneden, as is well known, viewed the two nuclei concerned as half nuclei male and female respectively, the union of which produced an entire nucleus of hermaphrodite nature. Weismann, on the other hand, speaks of "the union of the nuclear substance of the maternal and paternal individual." Strasburger has shown that in the fecundation of phanerogams the nucleus alone of the sperm cell (pollen tube), not the cell body also, enters the embryo sac to conjugate with the nucleus of the ovicell. Strasburger, led by Van Beneden's results, concluded that the occurrence of heredity depends on the transmission of a nuclear substance of specific molecular structure. This specific nucleo-plasma of the germ cell is what Weismann terms germ-plasma. This germ-plasma is, however, by no means identical with Nägeli's idioplasma. The idioplasma, according to Nägeli, is a network which stretches through the entire body, and in fact constitutes the specific molecular basis determining its manner of the body's existence. The general conception of a molecular basis of the organism governing its existence and opposed to the mere nutrient plasma is a fine and original one, and worthy of much merit, but in its detailed development Nägeli's theory cannot now be accepted. Even if the cell bodies are everywhere connected by fine outgrowths in all vegetable and animal pluricellular organisms, as recent research seems to show, the network present is one of nutrient plasma, not of idioplasma, for the determining molecular basis is confined to the nuclei which are not so connected. Moreover, there can be no one single substance such as idioplasma of identical composition permeating the whole body. On the other hand each different kind of cell in each organism must contain its specific kind of idioplasma, or rather nucleo-plasma regulating its peculiar mode of existence.

The author quite agrees with Strasburger in considering the "specific peculiarities of organisms as centred in the cell-nuclei," and also in many points in his statement that "from the nucleus issue forth molecular stimuli into the surrounding cytoplasma, which, on the one hand, govern the processes of change of material in the cells, and, on the other, give to the growth of the cytoplasma conditioned by the nutrition, a certain character peculiar to the species." A valuable confirmation of this position is afforded by A. Gruber's experiment on Infusoria, that, though artificially separated fragments of Infusoria without any portion of the nucleus can live for some time, they never are able to regenerate themselves, whereas fragments containing part of the nucleus always do so. The nature of the nucleo-plasma undergoes a regularly ordered series of changes during ontogeny. The simplest view to take is, that at each division of the nucleus the specific plasma of the nucleus divides itself into two halves, differing in their essential composition, so that each resulting cell-body also, its character being determined by the nucleus, becomes re-fashioned. Thus, in the case of any Metazoon, for example, the two first segmentation spheres would undergo such change that the one would contain only the tendencies of heredity of the endoderm, and the other only those of the ectoderm, and so on throughout. Against such a supposition, however, stands the fact that is observed in instances of indirect division of nuclei during the process of kariokinesis, each mother nuclear loop of the nuclear plate splits exactly in two lengthways into two halves. Each daughter nucleus thus receives exactly the same supply of these, and it would appear as if the two nuclei could not differ, but must be exactly identical. Strasburger, therefore, considering this identity a fundamental fact, concludes that the difference between the two must arise subsequently to their separation as the effect of unlike nutrition. It is urged by Weismann, in antagonism to this view, which would be fatal to his theory, that all that is really proved by the fact is that at every division of a nucleus an equal mass of maternal and paternal nuclear substance passes to form each daughter nucleus, but that it is by no means shown that the quality of the parent nuclear plasma must be identical on both sides. On the other hand, from the effect of the daughter nuclei on their respective cell-bodies, which are most commonly different both in size and texture, it seems proved that they are usually different in quality. As well-marked examples may be cited the polar vesicles. In the case of some Mollusca the egg gives off, by the indirect method of nuclear division, two polar vesicles, one after another, and each of these divides into two. The four polar vesicles perish, whilst the nucleus of the ovum remaining in the yolk combines with the sperm nucleus, and, making use of its own cell body, becomes the embryo. The reason for the difference here must be that the quality of the nucleus of the polar body is different from that of the ovicell.

In accordance with Nägeli's views, then, the molecular structure of the germ-plasma must be so much the more complicated the more complex the organism is which is to be developed out of it: and further, it can be stated that the nuclear substance must become successively less and less complicated as ontogeny proceeds, in proportion as the foundations which yet have to be evolved out of any cell and of which the nuclear plasma is the molecular expression, become gradually less in number. The general nucleo-plasma becoming thus gradually more and more simple in molecular structure, soon loses its capability of reproducing the entire organism; it cannot by any process be metamorphosed back again into the immensely complicated germ-plasma. Only the nucleo-plasma of the original segmentation nucleus is germ-plasma—that is, possesses the structure by the regulating action of which on the process of growth the entire organism can be evolved. In many cases, from the moment of the first division of the ovum into two blastomeres the one blastomere loses the power of reproducing the whole organism out of itself alone, since one resulting blastomere represents the future epiblast, the other the hypoblast. Somatic nucleo-plasma cannot become converted into germ-plasma.

Phylogenetically the germ cells did not originate at the termination of ontogeny, but at its commencement, as is well shown by the conditions existing amongst certain lower chlorophyll containing organisms such as Pandorina and Volvox. The phyletic origin of the first germ cells must evidently be sought amongst the earliest polycellular organisms differentiated by division of labour. In the genus Pandorina of the Volvocineæ no such division of labour has as yet arisen; each spherical colony is composed of exactly similar flagellate cells (each with an eye-spot, chlorophyll contents and pulsatile vacuole) embedded in a common colourless jelly (*homoplastide*). These colonies reproduce themselves alternately by asexual and sexual process; in the latter case the copulating individuals are not yet distinguishable from one another as male and female; in either case every cell of the colony remains as yet a complete unicellular organism capable of separate reproduction. In Volvox, another genus of the same family, a *heteroplastid* condition has been attained and the separation into somatic and generative cells has been effected. The spherical colony consists of two sorts of cells—numerous small flagellate cells and much fewer large germ cells devoid of flagella. The latter alone can effect the production of a new Volvox sphere and can do this in two ways, either asexually (parthenogenetically) or after impregnation by small actively-moving spermatozoa formed out of certain of their own number. Now, as Kirchner has shown, the germ cells become separated off from the somatic cells early in the segmentation of the volvox ovum before the escape of the young heteroplastid from the egg-coverings, which is exactly as should be according to Weismann's views.

Here is proof that there is no intervention of somatic cells in the course of growth between the parent germ-cell and the daughter germ-cells, but that the latter arise directly from the parent germ-cell, and thus the continuity of the germ plasma is established as a fact for the commencement of the phyletic development series. In later times, with increasing complexity of the organism, the time of the separation of the germ-cells became gradually more and more postponed in most cases, and at the present period often occurs quite late at the end of the entire ontogeny. If in the egg of Diptera the first two nuclei which separate themselves by division from the segmentation nucleus of the egg form the reproductive cells, this is a proof that they receive the entire germ-plasma of the segmentation nucleus unchanged.

There are, however, scarcely any theoretical grounds against the supposition that unmodified germ-plasma might be mingled with the nuclear substance of the somatic cells; on the other hand, it would appear *a priori* very conceivable that all somatic cells might contain some unmodified germ-plasma. The fact that a complete Begonia plant with fruit and fertile seed can be grown from a Begonia leaf, whilst in the case of many other plants no such result can be obtained, seems to show that in certain plants the cells, or perhaps only certain cells, of the leaf contain germ-plasma, whilst in others unchanged germ-plasma is not present in the leaves at all, or in very minute quantities only. In the case of the mosses, where almost every cell of the roots, leaves, and axial shoots can become a complete plant, probably all, or nearly all, the component cells must contain an adequate supply of germ-plasma.

The Meaning of the Polar Vesicles.—The egg-cell must contain two kinds of nucleo-plasma or idioplasma, namely, germ-plasma and histogenetic plasma. During its growth it has to accumulate yolk and to form surrounding membranes, in some cases to form a micropyle, and otherwise adapt its cell-body to the production of the future embryo. Therefore, besides the germ-plasm it carries, it requires another kind of specific nucleo-plasma just like every other histologically differentiated cell. This histogenetic plasma cannot be the same as that which subsequently governs the development of the embryo, and which arises from the infinitely complex germ-plasma. As soon as the egg is ripe for fertilisation it is necessary that the histogenetic plasma should be got rid of, in order to leave the germ-plasma free to act, and the extrusion of the polar bodies is the removal of this *ovogenous* nucleo-plasma. This is an entirely new theory as to the significance of the polar bodies, and directly opposed to all those which would see the extrusion of a male element in the act.

In the case of the male sperm-cell, also, two kinds of nucleo-plasma are present—germ-plasma and spermogenous nucleo-plasma. As soon as the spermatozoon is ripe, the spermogenous nucleo-plasma is cast off as the equivalent of the polar body. Strasburger has lately described a large number of instances amongst plants of different groups, in which processes resembling the extrusion of polar bodies accompany the ripening of the generative elements of both sexes. And it is probable that similar conditions will in time be discovered to exist in other plants.

On the Nature of Parthenogenesis.—The fact of the formation of the polar bodies, considered in the light of the theory of the sexuality of the germ cells, has been freely made use of to explain the occurrence of parthenogenesis. Balfour suggested "that the function of forming polar cells has been acquired by the ovum for the express purpose of preventing parthenogenesis." Weismann naturally cannot agree with this view, since he regards the extrusion of polar bodies merely as the removal of the ovogenous or spermogenous nucleo-plasma. At the time his memoir was written there were no instances in which it had been ascertained with absolute certainty whether polar vesicles are formed or not in the case of ova about to develop parthenogenetically; but in a postscript at the end of the memoir he is able to announce that he has discovered that in the case of parthenogenetic summer eggs of the Daphnidæ a polar vesicle of distinct cellular structure occurs. This is sufficient proof of the incorrectness of the older theory, and he further adduces the fact that in the case of the honey-bee the same identical egg can be made to develop either after fertilisation or parthenogenetically, according to the act of the queen, showing that the parthenogenetic and sexual eggs are of the same essential nature. The difference between the two must lie in the quantity of germ-plasma which they respectively contain. In order that the segmentation nucleus of the ovum may proceed to the process of ontogenesis, it must possess a certain mass. Even amongst higher vertebrates it is known that an unfertilised egg may occasionally go through the first few stages of segmentation, then, however, always failing through lack of the requisite power.

When impregnation takes place and the substance of the nucleus of the sperm-cell becomes added to that of the ovum, the combined mass of germ-plasm becomes powerful enough to carry through all the stages of ontogeny to the end. In the case of certain animals where the ovum remains unfertilised, and thus unchanged after the extrusion of the ovogenous nucleo-plasma, if a special supply of nourishment reaches its germ-plasma, this increases in amount by growth, and thus attains the mass requisite to start the ontogenetic process, with the result that parthenogenetical development takes place. In the ordinary sexual process it is the sudden doubling of the mass of the nucleus by the copulation that starts the segmentation of the ovum. It is the increase of the mass of the nucleus which gives the stimulus to segmentation, the disposition to which was already there before. The difference between eggs requiring fertilisation, and those not requiring it supervenes after the ripening of the egg and the extrusion of the ovogenous plasma. The phyletic inheritance of the capability of parthenogenetic development rests on a modification of the power of growth of the egg nucleus.

More than ten years ago Weismann expressed the conviction that "the physiological value of the sperm-cell and egg cell are identical," and now that the body of the egg cell can hardly have ascribed to it a higher value than that of a common nutrient ground for the two nuclei during the act of impregnation, this position seems a very secure one, Strasburger fully agrees, and states that "Sperm-nucleus and egg-nucleus do not differ in their nature." If it were possible to introduce by artificial means into any egg, immediately after the change of the germinal vesicle into the egg-nucleus, the egg-nucleus of another egg of the same species, it is probable that the two nuclei would copulate just as if a ripe sperm-nucleus had penetrated into the egg in the usual way, and a direct proof would thus be given that the egg and sperm-nucleus are in fact identical. The technical difficulties are too formidable to permit of this experiment being made, but a partial confirmation is afforded by Von Berthold's discovery that in certain algæ Ectocarpus and Scytosiphon, not only a female, but also a male parthenogenesis occurs. Further, the occurrence of conjugation must be regarded as a proof of the correctness of this view. There can scarcely be any further doubt that conjugation is the sexual reproduction of unicellular organisms. Amongst these usually the two conjugating cells are externally absolutely alike, and probably they are so internally also, but there are some low forms, such as Volvox, where a difference between the two is already fully established, huge egg shells and minute zoosperms being produced. The identity of the sperm nucleus and egg nucleus here insisted on only regards their essential fundamental structure and composition; each is in certain finer details necessarily peculiar, as transmitting the idiosyncracies of its own parent stock.

H. N. MOSELEY

THOMAS ANDREWS, F.R.S.

DR. ANDREWS, whose death we announced a fortnight ago, was a native of Belfast (born December 19, 1813), and spent his whole life there. His father was a linen-merchant, in good position; and he received his early education at the Academy and at the Royal Academical Institution of Belfast. Thence he went to Glasgow, where he studied under Dr. Thomas Thomson, the well-known Professor of Chemistry, and learned practical work in his laboratory. He had, next, a successful undergraduate career in Trinity College, Dublin; where he distinguished himself in Classics as well as in Science. Having spent some time in Paris, in the laboratory of Dumas; and having obtained his Medical Degree in the University of Edinburgh, in 1835; he devoted himself to medical practice in his native town. In this he was highly successful; but he continued to devote his leisure, small as it was, to scientific research; publishing numerous papers on chemical and physical subjects. To these we will recur, but it is noteworthy that in 1844 he received one of the Royal Medals, in the gift of the Royal Society, for his purely scientific discoveries, before he finally gave up professional practice. He was the first lecturer appointed to teach Chemistry in the Royal Belfast Academical Institution, and he resigned this post, as well as gave up practice, when appointed in 1845 to the Vice-Presidentship of the "Northern College," now Queen's College, Belfast. The Presidents and Vice-Presidents of these new Irish institutions were appointed some years before the Colleges were opened, or the Professors elected, in order that the Government might have their advice and assistance in maturing the whole scheme. Andrews was thus associated with another justly-distinguished Irishman, Sir Robert Kane; and it is mainly to their labours and foresight that the Queen's Colleges, when at last opened, appeared before the world in full working order.

It had been understood from the first that Andrews was to be the Professor of Chemistry in Belfast; but, when the time for appointing Professors arrived, he was required (as a matter of form, merely) to produce a few Testimonials. These he obtained at once, in the highest terms, from such men as Thomas Graham, Humphrey Lloyd, MacCullagh, &c., and they need not be given here. But it may be interesting to show, as briefly as possible, the opinions of two of the greatest of foreign chemists. Liebig wrote (November 10, 1845) as follows:—"Ich hege die volle Ueberzeugung dass der Platz um den Sie sich . . . bewerben, keinen würdigern Besitzer finden dürfte. Sie haben viele Jahre hindurch mit den grössten Schwierigkeiten zu kämpfen gehabt, um der warmen Neigung welche Sie für die Naturwissenschaften hegen Nahrung zu geben, und weit entfernt dass Ihr Muth und Eifer dadurch gelähmt worden wäre, haben Sie durch Ihre letzten wichtigen Arbeiten über die Wärme bey chemischen Verbindungen dargethan, dass die Beschäftigung mit der Wissenschaft ein Bedürfniss ihres Geistes ist." Dumas (November 29, 1845) wrote:—"Vos titres à la nouvelle fonction à laquelle vous aspirez sont si clairs et si évidents que je ne concevrais guère que vous n'y fussiez point appelé . . . mais, tout en enseignant la chimie, n'oubliez pas que vous comptez au nombre des physiciens distingués de votre pays." The rest of this letter is not personal, but refers to the impossibility of separating chemistry from physics, and to the important aid which each of these sciences constantly obtains from the other.

Andrews was as successful in his Professorship as he had formerly been as a Practitioner. He soon gathered large classes, alike for general chemistry and for practical laboratory work. All his spare time, for the greater part of every working day, was spent in his private laboratory. Here he delighted to receive his scientific friends, and to engage eagerly in conversation with them while his hands were busy with the steady, deliberate construction or adjustment of apparatus for his next research. His habits were of an extremely temperate, almost abstemious, character. From his early breakfast, to his somewhat late dinner-hour, he never partook of either food or drink: and used to say that a man required only two meals a day. It is to be feared that his persistence in this habit in his later years tended materially to reduce his strength.

He was elected to the Royal Society in 1849. In 1852 (at Belfast), and again in 1871 (at Edinburgh), he presided over the Chemical Section of the British Association. He was President of the Association in 1876 (at Glasgow), having declined the appointment in a former year in consequence of the state of his health. He was a corresponding member of the Royal Society of Göttingen and an Honorary Fellow of the Royal Society of Edinburgh. He received honorary degrees from various Universities. But he valued this class of distinctions simply as tokens of the esteem and good wishes of the donors; and in the somewhat delicate matter of a civil title he shared the opinion, and followed the practice, of his cherished friend Faraday. In 1879 he resigned his appointments in Queen's College, and thenceforth led a very retired life, though still vividly interested in the progress of science, till his death on November 26 last.

The only purely literary works of Andrews, so far as the writers of this notice are aware, were his two extremely thoughtful and learned *Chapters of Contemporary History*. The first, entitled *Studium Generale*, was published in 1867, when attempts were being made to cripple the usefulness of the Queen's Colleges. The reasons for the appearance of the second, published in 1869 with the title *The Church in Ireland*, are still too painfully prominent to require special mention.

Dr. Andrews married, in 1842, Jane Hardie, daughter of Major Walker, of the 42nd Highlanders. He is survived by his widow, by three daughters, and by two sons, the elder of whom is Major in the Devonshire Regiment, and the younger a member of the Irish Bar.

His first published paper on a chemical subject is on the composition of the blood of cholera patients. He showed that it differed from normal blood only by having a smaller proportion of water. Much more important both in itself and as showing the bent of his mind to the borderland between Chemistry and Physics is a paper on galvanic cells with strong sulphuric acid as the exciting liquid. The question is of course really that of the electrolysis of strong sulphuric acid, and Dr. Andrews showed that the composition of the gas given off at the cathode varies in a remarkable manner with the temperature. This is quite in accordance with what we now believe as to the constitution and dissociation of strong sulphuric acid, but at the time the paper was written nothing was known which could lead any one to suspect such a variation.

We now come to one of his great works—the determination of the heat evolved during chemical action. In three series of investigations he determined the heat given out in the formation of neutral, acid, and basic salts, by the action of acid on base; in the displacement of one metal in a salt by another; in the formation of oxides; and in the formation of chlorides. In this great research we see the character of the man, his clear view of what was to be observed, his distinct recognition of the sources of experimental error, and the simple but effectual means he took to get his results free from the effects of such disturbing causes. Especially worthy of note is his use of solutions so dilute that further addition of water produced no sensible thermal change.

The well-known experiments of Favre and Silbermann were published not long after Andrews' first papers on this subject. It is interesting to notice that where these observers differ from Andrews, subsequent investigations, particularly those of Berthelot and of Thomsen, have shown that Andrews was right.

In 1855 Andrews communicated to the Royal Society a paper of great importance and interest on Ozone. This remarkable substance had been studied by Schönbein, its discoverer, Marignac, De la Rive, Berzelius, Williamson, Fremy and Becquerel, and Baumert, but its nature still remained a mystery. Is ozone always the same thing, or are the ozone of electrolysis, that of the electric machine, and that formed during the slow oxidation of phosphorus, different bodies very like one another in properties?

Some experiments seemed to show that ozone contained nothing but oxygen, others that it was an oxide of hydrogen containing a larger proportion of oxygen than water does. The question was exactly of the kind to attract Andrews and to call out his peculiar powers of investigation.

By a series of experiments remarkable for simplicity and delicacy, and perfect adaptation to the purpose in view, he proved that "ozone, from whatever source derived, is one and the same body, having identical properties and the same constitution, and is not a compound body, but oxygen in an altered or allotropic condition."

The investigation into the nature of ozone was continued by Andrews and Tait, and the results published in their paper *On the Volumetric Relations of Ozone and the Action of the Electrical Discharge on Oxygen and other Gases* (*Phil. Trans.*, 1860). These results led directly to the theory of the constitution of ozone now universally held; indeed that theory is distinctly stated by Andrews and Tait, although not further discussed on account of its supposed improbability.

Among smaller works we may mention the discovery of minute particles of metallic iron in various rocks, particularly basalts.

None of his chemical papers can be read without some new idea being communicated to the reader, however well acquainted he may be with the subject.

The investigation, however, by which Andrews is, and will continue to be, best known, was that *On the Continuity of the Liquid and Gaseous States of Matter* which formed the subject of the Bakerian Lecture in 1869, and again in 1876.

One of the earliest of Faraday's researches was devoted to the liquefaction of gases, and he succeeded with all but a few, which were in consequence, till very recently, distinguished as "non-condensable." But he expressed the conviction, founded on experiment, that even these could be liquefied by the conjoint action of sufficient pressure and sufficient reduction of temperature.

Another extremely ingenious experimenter, Cagniard de la Tour, had approached the subject from the opposite side; and had shown that liquids, such as water and sulphuric ether, could be changed into something which was certainly not liquid, by sufficient rise of temperature without any great increase in volume.

Regnault, also, had measured with his unrivalled precision the compressibility of various gases; and had called attention to the curious differences which they show in their modes of divergence from Boyle's Law. And Natterer, by employing pressures of some thousands of atmospheres, had arrived at other startling results.

The whole subject was in that chaotic state which naturally precedes the advent of the Kepler who is to marshal, under a few general statements, each intrinsically simple, the mass of apparently irreconcilable phenomena.

Andrews' classical researches completely effected this simplification. Guided by the results of Regnault, he selected carbonic acid as the substance whose behaviour was made the subject of exhaustive study through wide ranges of temperature and of pressure. He devised an extremely ingenious form of apparatus for the purpose, had the coarser metallic parts constructed under his own eye by a remarkably skilful mechanic; and himself made and calibrated the glass portions, purified with great care and skill the gas to be operated on, and finally fitted up the whole with unwearying patience.

The simpler and more prominent results of this splendid research may be briefly summed up as follows:—

(*a*) When carbonic acid is maintained at any temperature whatever *above* 30°·9 C., it cannot even in part be condensed into liquid by any pressure however great.

(*b*) If the temperature be *below* 30°·9 C., the gradual increase of pressure ultimately leads to liquefaction; but the pressure of the vapour in presence of the liquid is less as the temperature is lower.

(*c*) A cycle of operations, in Carnot's sense, can be performed on liquid carbonic acid in such a way that, during the first stage of the expansion we have optical proof of the existence of liquid and gas side by side in the same vessel; while on compressing again at a higher temperature, and finally cooling down to the original temperature and volume, the whole contents are once more liquid; though at no stage of the latter part of the operation is there any appearance of the joint presence of two different states of matter. It is this fact which suggested the title of the paper.

(*d*) The key to the explanation of observed deviations from Boyle's Law was furnished by his study of the isothermals of carbonic acid at temperatures not much above 30°·9 C. For Andrews's measurements show that the product of pressure and volume (which, by Boyle's Law, should be constant) diminishes with volume to a minimum, and thereafter rises rapidly as the volume is farther diminished.

Many other valuable results, such as the great compressibility of liquid carbonic acid, especially at temperatures near to 30° C.; the alteration of surface-tension of the liquid, and of its angle of contact with glass, as the temperature is raised, &c., appear as mere side-issues of this investigation.

The discovery of this Critical Temperature, or Critical Point, soon led to the liquefaction (and in certain cases even to the solidification) of the gases which had been called "non-condensable." Andrews' work had supplied all the necessary hints for the adaptation of his apparatus to such a purpose. In fact the main requisites were (1) to work on a larger scale, (2) to employ very low temperatures, and especially (3) to provide a means of ensuring *sudden* relaxation of pressure. The work of Pictet, Cailletet, v. Wroblewski, Amagat, &c., on this subject, followed as a natural and immediate consequence of that of Andrews.

The writers have, like many others, seen and admired the confident manipulation, by Andrews, of wide sealed tubes, half full of liquid carbonic acid; how he, knowing the soundness of his own glass-blowing, boldly heated such tubes in the flame of a Bunsen lamp, till the liquid entirely disappeared, and pointed out with eager enjoyment the extraordinary phenomena presented as the contents cooled nearly to the critical temperature. The whole tube seemed, for a short time, to be filled with a substance presenting, to an exaggerated degree, the appearance of a mixture of water and alcohol before diffusion has sensibly operated.

We have spoken of Andrews's remarkable skill in manipulation, and of his unwearied patience. But even these were eclipsed by the perfect calmness with which, though on the very verge of an important discovery, he attended to every point of minute and laborious detail; so that his first successful experiment was as exactly carried out and recorded as was its future repetition. This was all the more remarkable in that he was usually, especially in public, a man of a highly nervous and excitable temperament.

An excellent French and German scholar, he kept himself always well acquainted with the most recent progress of science, whether chemical or physical. He constructed his own dividing-engine for the calibration of the exquisite thermometers which he made for his researches on heat; and his air-pump (in which he took special delight) was furnished with numerous valuable improvements all devised by him for particular applications. His laboratory books were models of ample, but not superfluous, detail.

He was, personally, a man of simple unpretending manner; conscientious almost to an extreme, but thoroughly trustworthy and warm-hearted; an excellent example of the true Christian philosopher.

NOTES

We regret to announce the death of Mr. Alfred Tribe, the well-known chemist, on November 26, at the age of forty-six years. We defer to next number a notice of Mr. Tribe's career.

A meeting of the subscribers to the testimonial to Dr. H. Woodward, F.R.S., for twenty-one years editor of the *Geological Magazine*, was held on the 15th inst., at the rooms of the Geological Society, Burlington House, when Prof. T. G. Bonney (Pres. Geol. Soc.) presented to that gentleman, on behalf of the subscribers, a silver tea and coffee service and a cheque for 253*l*. On making the presentation, Prof. Bonney addressed Dr. Woodward, referring to the invaluable services he had rendered to science during the twenty-one years he has had charge of the *Geological Magazine*. In replying, Dr. Woodward referred briefly to the career of the *Magazine* and its predecessors, to the many distinguished men that had been connected with them, and to the period of remarkable scientific interest thus covered. Over 200 names are on the list of subscribers to the testimonial.

The 10th instant was a red-letter day at the French Institute. M. Bertrand was introduced as member of the Académie Française, and read an address which, according to custom, was devoted entirely to thanking his brother Academicians and to eulogising his immediate predecessor, M. Dumas. The address was acknowledged by another oration from M. Pasteur, who after having summarised the life of M. Bertrand, gave a long and interesting account of the career of M. Dumas. Great enthusiasm prevailed throughout the proceedings, and the hall was crowded.

The number of patients in the special clinic of M. Pasteur is increasing daily, several arriving from foreign countries. No less than forty were inoculated on December 14 before the Minister of Agriculture, who acknowledged the services rendered by Pasteur to humanity. Among the patients is an officer of the Czar's body-guard, just arrived from St. Petersburg.

A biography of the late Sir William Siemens is being prepared, at the desire of the executors, by Dr. William Pole, F.R.S., Hon. Secretary of the Institution of Civil Engineers, and author of the "Life of Sir William Fairbairn, Bart." Dr. Pole will be grateful for the loan of any of Sir William's letters, or for any information of importance. Address, Athenæum Club, S.W.

On Saturday, last week, the rainfall at the Ben Nevis Observatory amounted to 4·991 inches, and on the Sunday following to 3·604 inches, there having thus fallen on these two days fully eight inches and a half. During this time the wind was westerly and north-westerly, force 2 of Beaufort's scale, with occasional squalls. On the Monday the wind was still westerly, and though no rain fell from 2 a.m. to 10 a.m., the rainfall for the twenty-four hours was 1·225 inch.

THE death is announced of Xavier Ullesberger, the well-known palæontologist, at Ueberlingen, on the Lake of Constance, at the age of seventy-nine. His special distinction is the discovery of the lacustrine villages in the Lake of Constance, at Nussdorf, Maurach, Uhldingen, and Sipplingen. The extensive collection of Celtic and prehistoric objects which he got together in the course of his researches is preserved at Stuttgart.

THE death of Mr. Edwin Ormond Brown, Assistant-Chemist to the War Department, occurred on Saturday last. Mr. Brown had been engaged in the chemical establishment at the Royal Arsenal, Woolwich, for about thirty years, and has been instrumental in the improvement of gun-cotton and other explosives, besides rendering useful services in other matters.

THE Earl of Iddesleigh gave a very sensible address the other evening to the students of the Exeter Science Classes, of which he is the patron. He spoke of the rapidly growing feeling in favour of scientific education, and of the results it had already accomplished for the individual and the nation. After referring to misconceptions as to what technical education really meant, the Earl said:—"There is no doubt that by technical education you may mean one of two things. You may either mean an advance in the teaching of the scientific principles on which industrial processes depend, or you may mean the teaching of those processes practically and illustratively in the school rather than in the workshop. There is a very great difference between these two things. It may be desirable at times to give a certain amount of instruction in schools of a practical character, but that must not be pushed very far. It must be borne in mind that technical teaching, to be of real service, must be obtained in the course of work itself in the workshop. But with regard to the principles on which the processes of manufacture rest, those principles can only be taught in the schools, and it is to the development of those principles that we ought to pay most attention. That is the advantage which in schools of this kind you get. The study of pure and unapplied science is interesting to every one, but it does not at once appear that it has a direct bearing on the pursuits and callings of those who indulge in it. I daresay you may have heard the old question put, 'What is the use of any purely scientific discovery?' For answer another question was asked, 'What is the use of a baby?' The question is, What will it turn out to be? How will it be brought up, and how will it be brought into play?" The Earl of Iddesleigh then quoted the following passage from Prof. Huxley:—"'If you could, in the first place, keep your elementary scholars long enough to put them through a fair training in the principles of which the application lies in the special direction of metallurgy, and, secondly, if you could secure that they should acquire a special proficiency in such subjects, I think that would be a most admirable thing to do; but I thing the way it would work out under the present conditions would be this, that you would have special classes set up to grind young fellows without any knowledge of principles in that which would be no better than a rule of thumb. I do not believe that that would be of the smallest good. I believe, on the contrary, that it would do endless harm, because there would be a sort of pre-supposition that these young men really had the knowledge which would enable them to advance and improve their methods, whereas in reality the knowledge they possessed would be nothing more than a little of the ordinary *technique* of their business varnished over with scientific phraseology.' What you want," the Earl said, "is what Prof. Huxley says you want, as far as you can get it—the education to turn upon the principles on which the true science is based, as distinguished from the application of the science. Having got that, you will find that there will be abundance of opportunity to apply to the arts which you are about to prosecute the principles you have learnt. These principles I believe to be the main secret of what is sometimes called scientific, and sometimes called technical, education."

THE Royal Geographical Society will hold a special meeting on Monday, December 21, to welcome Major Greely, the distinguished Arctic explorer, and hear him tell the story of his work and adventures in the Polar Seas.

THE Natural History Museum at Vienna has just been presented with 708 skulls collected through a series of years by Dr. Weissbach, who was for a long time director of the Austro-Hungarian hospital at Constantinople, and was a very distinguished anthropological investigator. Of the collection 195 are pure Turkish skulls, 131 Greek, 96 Servian or Croat, 48 Hungarian, 43 Armenian, 29 old Byzantine. There are also skulls of Maronites, Albanians, Koords, Asiatic Jews, &c.

AS No. 1 of the Special Papers of the Alabama Weather Service we have an interesting record of the weather from 1701 to 1885, by Capt. W. H. Gardner, of Mobile.

SCIENCE has, on the whole, no reason to quarrel with the results of the General Election. Sir Lyon Playfair is returned by a large majority for one of the divisions of Leeds; and Sir John Lubbock again takes his seat unopposed for London University. A new and very important additiou to the ranks of scientific men in Parliament is Sir Henry Roscoe, who was elected after a sharp contest for South Manchester. His election is striking in one way, for he is the only Liberal returned in the six divisions of Manchester. Sir Edward Reed retains his former seat for Cardiff, but Prof. Rücker, of the Yorkshire College, failed to win a place. The medical profession is even more strongly represented than it was before. Dr. Foster, Professor of Medicine in the Queen's College, Birmingham, was elected for Chester, and Mr. Erichsen, the eminent surgeon, is a candidate for Edinburgh and St. Andrews Universities. Even amongst the followers of Mr. Parnell, there are members of the medical profession. Mr. Ernest Hart, however, has been rejected by Mile End.

WE have received the last part (vol. i. part 5) of the *Proceedings* of the Perthshire Society of Natural Science for the session 1884–85. It contains a series of museum notes, by Dr. Buchanan White, the indefatigable President for the current year, which are intended to form a guide to the museum subsequently; two papers on the comparative anatomy of the teeth, by Mr. James Stewart; the diatoms of the Tay, by Dr. Trotter; shells—their structure, growth, and use, by Mr. Coates; the climate of the British Islands, with special reference to Perthshire, by the Rev. A. Campbell; the native timber trees of Perth, by Mr. Lindsay; and some minor contributions. The presidential address is devoted to the exceedingly practical subject of explaining why the growth of the museum renders considerable increase of space necessary, and the cost of the consequent building operations. An appeal is also made for further specimens for the Perthshire collection of natural history—an appeal which we trust may meet with adequate response, for apart from the general public benefit of local museums as centres of education throughout the country, they are of universal scientific importance when they are made the depositories of specimens of the natural history, past and present, of their respective neighbourhoods. But to be of the fullest value in this respect, they must be made as complete as possible.

MESSRS. MACMILLAN AND CO. will publish next week the Essex Field Club Report on the East Anglian Earthquake of April 22, 1884. This Report has been drawn up by Prof. Raphael Meldola and Mr. William White, and will contain maps and several illustrations.

THE jubilee volume of the Statistical Society will shortly be published by Mr. Stanford, of Charing Cross. It will contain the proceedings of the jubilee meeting of the Society held in June last, and will comprise valuable papers by the President, Sir Rawson W. Rawson, Dr. F. J. Mouat, M. Levasseur, and Prof. Neumann-Spallart, at whose initiation the International Statistical Institute was then founded.

FRESH earthquake shocks have been felt in the district round M'sila during the last week and principally on Saturday, December 12. They have also been felt at Bordj-ban-areridj and Setif. The new road from Setif to Bordj has been cut by rocks falling from the surrounding mountains. A bridge has been destroyed and a railway station demolished. It is impossible up to this time to state whether the commotion originated in the Atlas or in the Hodna region, where M'sila is placed, not far from a large Sebbha, which, although almost dry in summer-time, contains a large quantity of water in rainy periods. Official documents will be sent to the Paris Academy of Sciences as soon as collected, but it is feared they will lack precision; no seismograph, so far as our knowledge goes, having been established in Algiers.

ADVICES from Smyrna in Asia Minor to November 25 state that a series of earthquakes, commencing on the 13th, had up to that time been felt at Denizlu in the interior, about 200 miles to the east. These disturbances were slight, but accompanied with subterranean noises.

WE are glad to see that the extremely valuable meteorological observations which were made at Sagastyr, the Arctic Station in the Delta of the Lena, during the years 1882 to 1884, are already being published. The last issue of the *Izvestia* of the Russian Geographical Society contains a preliminary report, by M. Yurgens, and several meteorological tables, namely, the observations in full, from September 1, 1882, to September 1, 1883, of the barometer, temperature of the air, of the surface of the soil and of the snow, and of the soil at a depth of 1 metre, the relative humidity, force of wind, and nebulosity; and the monthly averages of the above for each hour of the day. The magnetical observations for the same period are being calculated, as also those for 1883 and 1884. The whole, together with observations of the temperature of the soil at depths of 80 and 160 centimetres, temperature and density of water, tides, and auroræ will be published in a separate form. A map of the Delta of the Lena, based on new surveys, and a plan of the station accompany the report of M. Yurgens, which is very interesting, as it contains many details as to the life at the station, and varied information as to the Delta, and the excursions made during both summers. It is worthy of notice that the meteorologists of the station, although lost amidst tundras in the 73rd degree of latitude, were not so secluded from the world as might have been supposed. They received letters regularly from Yakutsk, together with newspapers and reviews, which reached them four months after their publication at St. Petersburg—a delay which is not so great if it be taken into account that letters take nearly one month to reach Irkutsk, the capital of Eastern Siberia. As to the frozen mammoth whose remains were explored by Dr. Bunge, only pieces of bones and traces of the contents of the stomach were found and brought to St. Petersburg.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀), two Grey-breasted Parrakeets (*Bolborhynchus monachus*) from Monte Video, presented by H.R.H. the Prince of Wales, K.G.; two West Indian Agoutis (*Dasyprocta cristata*) from West Indies, presented by T.R.H. Prince Albert Victor and Prince George Frederick of Wales; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. Jan Smidt; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Miss Ethel Rodger; two Tigers (*Felis tigris*) from Hyderabad, presented by the Nawab Salar Jungh Bahadur; a Cheetah (*Cynælurus jubatus*) from Afghanistan, presented by the Nawab Mahomed Hassan Ali Khan; a Tiger (*Felis tigris*).

OUR ASTRONOMICAL COLUMN

BRIGHT LINES IN STELLAR SPECTRA.—Mr. O. T. Sherman has continued his researches on the spectra of γ Cassiopeiæ and and β Lyræ, and announces in the *American Journal of Science* for December the discovery of no fewer than fifteen in the spectrum of the former star, and seventeen in that of the latter. The lines seen in γ Cassiopeiæ are as follows:—Hα, λ 6356, 6160, D_3, λ 5840, 5557·5, 5422, 5309·8, 5167·5, 4990, Hβ, λ 4623, Hγ, λ 4180, and Hδ, bright lines; and λ 6280, 5760, 5020, 4920, 4673·5, and 3993, dark lines. The bright lines agree closely in position with the principal lines observed by Prof. Young in the spectrum of the chromosphere.

Mr. Sherman has also examined a large number of other stars, and "*in each case* many or few bright lines have been seen, lines, so far as I know, formerly unsuspected." It is clear, if Mr. Sherman's observations can be satisfactorily confirmed, that we have here a most important discovery; but looking to the fact that these stars have probably been frequently observed by experienced spectroscopists without any bright lines being detected in them, whilst a false appearance of bright lines is readily produced in stellar spectra under certain circumstances, it would appear hazardous to accept Mr. Sherman's result without further evidence.

PHOTOMETRY OF THE PLEIADES.—A valuable memoir (*Mémoires de l'Academie Impériale des Sciences de St. Pétersbourg*, vii. série, tome xxxii. No. 6) by Herr Ed. Lindemann of Pulkowa, "On the Magnitudes of Bessel's Stars in the Pleiades," has recently reached us. A special point of interest lies in the fact that Profs. Pickering and Pritchard have likewise determined the brightness of many of these stars with their respective photometers, each assuming the magnitude of Merope, to which the other stars of the group are referred, as 4·22. Herr Lindemann has also adopted the same magnitude for Merope, which he has used as his standard star. He also employed, as reference stars, Celæno and Anon 32, the magnitudes of which he had determined to be 5·27 and 6·51 respectively. The stars, fifty-two in number, were each observed on two separate nights, only one star of the fifty-three observed by Bessel proving too faint for Herr Lindemann's telescope of five inches aperture. Comparing his own results with those of Profs. Pickering and Pritchard, Herr Lindemann finds, on the whole, a very gratifying agreement; twenty-five stars observed by Prof. Pickering showing a mean excess over the Pulkowa observations of 0·04 of a magnitude, and thirty-three stars observed by Prof. Pritchard giving a mean excess of 0·05. Prof. Pritchard's later observations give a yet smaller difference, viz. 0·01 of a magnitude. When it is remembered that the three photometers employed—Herr Lindemann using a Zöllner photometer—differed entirely in principle, construction, and method of employment, this close agreement would seem to indicate that each may be relied upon with very considerable confidence, when the differences of stellar magnitude determined by their means are not very great. The stars Nos. 1, 4, 21, 31, and 33 would appear to be variable, and possibly two others likewise. Pogson's scale has been employed for the conversion of the logarithm of the light of the star into magnitude.

FABRY'S COMET.—The following elements and ephemeris have been computed for this comet by Dr. H. Oppenheim:—

Perihelion Passage, 1886 March 9·7944 Berlin M.T.

$$\left.\begin{aligned}\omega &= 132^\circ\ 36'\ 19''\\ \Omega &= \ \ 32\ \ 17\ \ 32\\ i &= \ \ 47\ \ 18\ \ \ 0\end{aligned}\right\}\text{Mean Eq. 1885·0}$$

$$\log. q = 9·69654$$

Errors of the middle observation :—

$\delta\lambda = -8''$ $\delta\beta = -2''$.

Ephemeris for Berlin Midnight

1885	App. R.A. h. m. s.	App. Decl.	Log. Δ	Brightness
Dec. 20	23 59 57	+20 43·1	0·0837	1·4
22	56 49	44·3		
24	53 52	46·2	0·0844	1·5
26	51 5	49·0		
28	48 29	52·6	0·0849	1·6

The brightness on December 1 is taken as unity. The above elements differ considerably from those published by Dr. S. Oppenheim in the *Vienna Circular*, No. lvi., but appear to represent the observations better.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, DECEMBER 20-26

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 20

Sun rises, 8h. 5m. ; souths, 11h. 57m. 59·2s. ; sets, 15h. 50m. ; decl. on meridian, 23° 27′ S. : Sidereal Time at Sunset, 21h. 48m.

Moon (Full on Dec. 21) rises, 15h. 17m. ; souths, 23h. 5m. ; sets, 6h. 58m.* ; decl. on meridian, 17° 48′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	7 36	11 45	15 54	20 58 S.
Venus	10 47	15 17	19 47	17 41 S.
Mars	22 46*	5 25	12 4	7 2 N.
Jupiter	0 22	6 23	12 24	0 38 S.
Saturn	16 19*	0 28	8 37	22 29 N.

* Indicates that the rising is that of the preceding and the setting that of the following day.

Occultations of Stars by the Moon

,,			,, 25,	2 56	*m*

M signifies maximum ; *m* minimum.

Objects with Remarkable Spectra

Mr. O. T. Sherman, of Yale College Observatory, has recently called fresh attention to the spectra of γ Cassiopeiæ and β Lyræ, as he finds no fewer than seventeen bright lines in each. Both stars should therefore be examined as frequently and carefully as possible. β Lyræ is at minimum about midnight on Dec. 25.

There is an uncertainty about the ephemeris of R Andromedæ which renders observations of its brightness a matter of importance ; its spectrum, whilst resembling in several particulars that of the third type, possessing so many special characteristics, that it deserves the most careful attention directly the star has attained a sufficient magnitude.

THE RETURN OF THE LEONIDS IN 1885

Between November 5 and 13 inclusive we had densely overcast skies, so that no observations could be obtained here.

On November 14 weather improved, but it was not until the morning of the 15th that the clouds completely dispersed and enabled that uninterrupted view of the firmament which is so necessary to the successful recording of meteors. The three following nights were also brilliantly clear, though the severe frosts which occurred rendered open-air watching somewhat trying. I have summarised my results for the four mornings as follows :—

Date, 1885	Time of obs. a.m. h. h.	Actual duration of obs. h.	Meteors seen	Leonids	Radiant point ° °
Nov. 15	3½ to 6	2¼	24	4	149 +21
16	0¾ to 3	2	23	0	—
17	0¾ to 4¾	3½	42	6	150 +22
18	2¾ to 5¼	2¼	25	1	—
Nov. 15–18	0¾ to 6	10	114	11	149½ + 21½

Making certain allowances for the intervals occupied in registering the paths, &c., meteors fell at the rate of about 14 per hour for one observer. Of the total number seen 11 only belonged to the special shower of Leonids. The proportion of the latter to the meteors visible from all other streams was therefore as 1 to 10·4. Six of the Leonids appeared in Leo with much foreshortened tracks close to their radiant point, which admitted of very accurate determination. As usual, they left lines of phosphorescence which in several instances brightened most perceptibly about one or two seconds after the extinction of the nucleus. I have frequently noticed this after-glowing of the streaks which are so commonly generated by the swift meteors discharged from the radiants near the apex of the earth's way.

On the morning of the 15th the Leonid's furnished about two meteors per hour for one observer. On the 16th there was an apparent lull in the display, not one being observed. On the 17th there was a very distinct reappearance of the shower with the same relative intensity as on the 15th. On the 18th the shower had nearly become exhausted, for of 25 shooting-stars only one certainly could be assigned to the radiant in Leo.

It is extremely probable that the maximum took place, as it usually does, on the morning of the 14th, when unfortunately the sky was involved in clouds. But the observations now reported for the later nights of the display sufficiently prove there to have been a definite, though feeble, revival of the shower this year, and there can be no question that the Leonid meteor-orbit is continuous so far as our accumulating observations enable us to judge. Every November, as the earth crosses the node, meteors having the same radiant in the sickle of Leo are to be seen, and they exhibit all the characteristics typical of the Leonids during one of the major displays. There are doubtless some condensations in the orbit, giving rise to brighter showers in some years than in others, but a large number of further observations are required to determine the precise nature of these. There can be no doubt that there are certain occasions when fairly bright returns of these meteors pass wholly unobserved. Moonlight, cloudy weather, or the occurrence of a maximum in the daytime, may so much obliterate it as to induce entirely wrong impressions as to its comparative strength in successive years. We essentially require observers in widely different longitudes, and the continuity of annual records should be preserved as far as possible.

With regard to the display of the present year, the want of observations on November 12 and 13 will not allow us to form a safe judgment as to its character. Probably it has been below the average. As to the individual meteors recorded at this station, they were generally small, and, with one exception, need no comment. The brightest appeared at 5h. 3m. a.m. on November 15, and was estimated very nearly equal to Jupiter. Its path of 12° lay 5° south of β and γ Draconis, and it left a vivid streak there for about five seconds.

As to the numerous contemporary showers of this epoch, they are extremely interesting, and some of them were observed this year with unusual distinctness. In preceding years I have registered a considerable number of Taurids and Muscids at this epoch, but during my late observations not many were noticed. I was, however, watching a region of the heavens far removed from the radiant points of these showers—a fact which may in some measure explain the apparent paucity of their meteors. But on the 15th and 16th a few of the slow-moving Taurids were seen traversing long flights amongst the stars of Leo Minor and Ursa Major. At 2h. 20m. a.m. on November 16 one fell in a path of 17° slightly to the left, and very nearly parallel to the stars ζ and η of Ursa Major. It was brighter than Jupiter, and exhibited a small yellowish-white disk, varying in magnitude in a most curious manner. During its course the meteor appeared to halt and rekindle with increased impetus several times, and short trails of sparks were thrown off at the points of maximum brightness.

Below I give a summary of all the radiant points derived from my a.m. observations on November 15-18 last:—

No.	Radiant (° °)	No. of meteors	No.	Radiant (° °)	No. of meteors
1 ...	$149\frac{1}{2}+21\frac{1}{2}$ ...	11	7 ...	213+75 ...	8
2 ...	154 +41 ...	12	8 ...	157+74 ...	4
3 ...	166 +31 ...	10	9 ...	79+56 ...	6
4 ...	144 +50 ...	6	10 ...	73+42 ...	5
5 ...	125 +41 ...	6	11 ...	190+21 ...	3
6 ...	60 +28 ...	5	12 ...	100+41 ...	5

Nos. 2, 3, 4, and 5 are important. They severally furnish meteors of the swift streak-leaving class. No. 6 represents the centre of a few Taurids, and Nos. 7 and 8 are positions derived from slow meteors not very far from Polaris. Nos. 9 and 10 are a pair of sharply-defined radiants in Auriga, and No. 11 is an entirely new shower which I observed on the morning of the 17th and 18th. Only three of its meteors were recorded, but their paths intersect at a point, and I believe the position is reliable.

The radiant No. 2 at 154° + 41°, near μ Ursæ Majoris, is the best of all, and has often been seen in previous years. It is evidently the same as the "very active shower" described by me in NATURE, vol. xv. p. 158, as observed here from the point 155° + 36°, on November 20-28, 1876. It is also identical with the shower seen from 155° + 35° by Father Perry at Stonyhurst College Observatory on November 13-15, 1879 (*Monthly Notices*, January, 1880, p. 140). Not only in November, but in many other months, does this particular radiant point manifest itself. I have summarised the positions from September to December, though the shower is still sustained with equal definiteness until May:—

Radiant (° °)	Epoch	Observer or authority
155+41 ...	Sept. 8–October ...	D. From Zezioli's obs.
156+41 ...	September 15–16 ...	D. Obs. in 1877
153+42 ...	October 16	D. Obs. in 1877
152+38 ...	October 14	D. Obs. in 1879
160+40 ...	November 7, 1869 ...	Tupman (estimated)
149+38 ...	November 1–15, 1872	D. From Italian obs.
157+46 ...	November 11–15 ...	Denza
155+35 ...	November 13–15 ...	Perry. Obs. in 1879
154+41 ...	November 14–17 ...	D. Obs. in 1885
155+36 ...	November 25–27 ...	D. Obs. in 1876
154+39 ...	December 6–7	Backhouse
160+40 ...	December 8–9	Backhouse
152+43 ...	December 9–12... ...	D. From various foreign obs.
149+45 ...	December 9	Schiaparelli and Zezioli

The positions marked "D." are those resulting from my own observations or reductions. The two radiants at 160° + 40°, by Tupman and Backhouse, may possibly relate to another bordering shower, but the position is very close to the mean of all at

$$154°\cdot 4 + 40°\cdot 4.$$

This is a shower (or series of showers) which eminently stands in need of further investigation. The radiant appears to be stationary and continuous for a long period. The shower at 166° + 31°, 10° north of δ Leonis, which I detected this year, has escaped me before, though it was seen at Stonyhurst in 1879, November 13-15, at 166° + 22°. As to position No. 5 in my present list, I saw that well on November 12, 1877, at 125° + 40°. With reference to the radiant No. 4 at 144° + 50°. close to θ Ursæ, I have not recognised it in November until this year, but in October last I determined a good radiant at 143° + 49° from meteors seen in the morning sky.

These circum-Leonid streams reappear with more or less distinctness every year, and their radiant points are sharply defined. It would be well to thoroughly study the durations of several of them, now that their positions have been ascertained with a considerable degree of accuracy by several observers.

Bristol, November 19 WILLIAM F. DENNING

NOTES FROM THE OTAGO UNIVERSITY MUSEUM

VII.—*On some Models Illustrating Phyllotaxis*

PHYLLOTAXIS is a subject which presents special difficulties to the student when illustrated only by diagrams and by actual specimens of plants. With these aids alone it

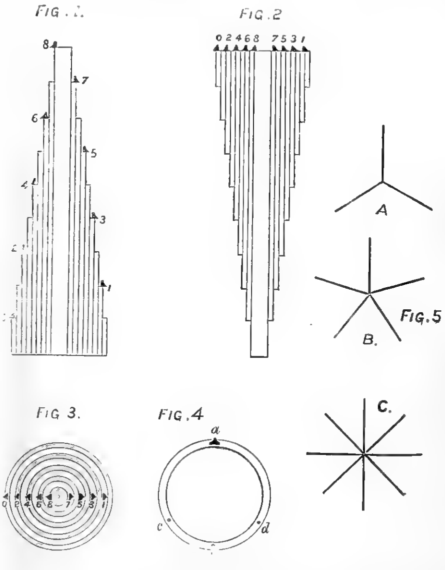

FIG. 1.—Vertical section of model, one-eighth actual size; 0-1, the leaf knobs.

FIG. 2.—The same, telescoped, the upper edges of all the cylinders being brought to one level.

FIG. 3.—The same, telescoped, and viewed from above.

FIG. 4.—One of the cylinders from above: *a*, the fixed leaf-knob; *b*, *c*, *d*, holes for the insertion of movable knobs

FIG. 5.—Wire stars to represent orthostichies: A, for divergence of one-third; B, for two-fifths; C, for three-eighths.

entails an expenditure of time, out of all proportion to the importance of the subject, to make clear in a lecture or demonstration the principles of leaf-arrangement and the mode of construction of the leaf-diagram.

I find the model about to be described of great assistance in explaining these matters. It consists of a "nest" of nine concentric cylinders, made of some hard wood (Fig. 1), the outermost 2 inches high, the others increasing in height by regular increments of 2 inches up to 18 inches. The cylinders are $\frac{1}{4}$ inch thick, except the innermost, which is a solid rod 1 inch in diameter: they are made so as to slide easily upon one another in any direction. The exposed portion of each cylinder, 2 inches in length, represents an internode, its upper edge a node. On the upper edge of each is fixed a small wooden knob (Fig. 1, 0–8) representing a leaf-insertion, and of such a size as to project slightly beyond the cylinder to which it is attached. By revolving the cylinders these knobs can be made to take up positions representing any divergence from $\frac{1}{2}$ to $\frac{3}{8}$; higher divergences would of course require a greater number of cylinders and consequently a larger and more unwieldy apparatus. In the figures the cylinders are shown adjusted to a divergence of $\frac{1}{2}$. The adjustment is facilitated by holding above the model a straight wire in the case of $\frac{1}{2}$ divergence, or a 3-, 5-, or 8-rayed wire star (Fig. 5, A, B, C) in the case of higher divergence. The genetic spiral is best shown by winding a piece of string round the model.

To explain the construction of the leaf-diagram, the whole apparatus is "telescoped" by simply lifting the lower cylinder: as the latter is raised each cylinder in turn is caught by the projecting portion of the leaf-knob of the next higher cylinder, until finally the upper edges—*i.e.* the nodes—of all nine are brought to one level, or in other words, the internodes are suppressed (Fig. 2). Then by observing the model end-on (Fig. 3), nine concentric circles are seen, each representing a node, and having a leaf-insertion in the appropriate position. To make this clearer, the upper edges of the cylinders are painted alternately light and dark, as in Fig. 3. The resemblance of the model in this position to the leaf-diagram is made still clearer by placing over it a straight wire or wire star (Fig. 5) to represent the orthostichies, and bring out the precise meaning of the angle of divergence.

For the illustration of whorled arrangements movable leaf-knobs are provided which can be inserted in small holes (Fig. 4, *b*, *c*, *d*) in the edges of the cylinders. By placing one of these movable knobs in *b* opposite to the fixed knob *a*, a 2-leafed whorl is produced; by placing knobs in *c* and *d*, a 3-leafed whorl. By revolving the cylinders successive whorls can be made either alternate or superposed.

I tried at first, some four years ago, a model having all the cylinders of the same height, each fitting rather tightly into the next lower one, which overlapped it about half an inch. But I found it impossible to get this arrangement to work satisfactorily, owing to the irregular contraction and expansion of the wood and the weight of the upper cylinders.

In addition to this model I find it very useful to have each divergence separately illustrated by a model having the form of a truncated cone 18 inches in height. The cone is painted white: black circles are drawn round it at regular intervals to represent nodes, on which black knobs are fixed for leaves: the orthostichies are painted yellow, and the genetic spiral red. In the case of the higher divergences these models are useful for showing the relations of the parastichies and the method of determining the divergence from them. Two secondary spirals running in opposite directions are made by passing two pieces of differently coloured string round the cone in opposite directions, each having a turn given to it round each leaf-knob in the parastichy it represents. T. JEFFERY PARKER

Dunedin, N.Z., October 9

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Dr. Vines has been appointed Honorary Secretary of the General Board of Studies for business connected with the lists of lectures issued by the Board.

Dr. A. S. Lea, Fellow of Gonville and Caius College, has been approved for and admitted to the degree of Doctor in Science.

A temporary iron dissecting-room for Human Anatomy is to be erected on space adjacent to the present Anatomical Schools. Over 145 men are engaged in dissection this term.

The honorary degree of Master of Arts has been conferred on Mr. Walter Heape, Demonstrator of Animal Morphology.

The Public Orator (Mr. J. E. Sandys), in presenting Mr. Heape for the degree, observed that Mr. Heape, *quantum inter lucrum et laudem intersit expertus*, had relinquished the brilliant prospects open to him in a mercantile career and had deliberately preferred to devote himself to scientific pursuits. In 1879 he was attracted to Cambridge by the high reputation of the late Mr. F. M. Balfour, and after working with him for three years in the newly-founded Morphological Laboratory, he had, during the three years that had elapsed since Prof. Balfour's lamented death, done good service as Demonstrator of Animal Morphology. In prosecuting his favourite studies he had considered nothing too small, nothing too great, for his attention; he had not only investigated the early development of the mole, but had also secured for the University Museum an exceedingly rare specimen of a wild male African elephant, which he had killed with his own hand in the South of Africa. "Magnum profecto est ultimâ ex Africâ spoliis opimis onustum redîsse; laudem vero majorem eidem distinat virtus—

> "Diadema tutum
> Deferens uni, propriamque laurum,
> Quisquis ingentes oculo irretorto
> Spectat acervos."

An examination for two minor Scholarships will be held at Downing College on June 1, 2, and 3, 1886. The examination in Natural Sciences will include most of the subjects of the Natural Sciences Tripos except Geology and Mineralogy, but no one will be examined in more than three subjects, and great weight will be attached to proficiency in one subject.

The Clothworkers' Exhibition of 52*l.* 10*s.* a year for Physical Science has been awarded to Mr. G. A. Shaw; the Exhibition of 30*l.* to Mr. J. Morgan.

The Antiquarian Museum is growing in value by the donations, both general and local, which it has received. The Curator, Baron von Hügel, has accomplished much in the arrangement of the objects, and has himself deposited valuable collections on loan.

SCIENTIFIC SERIALS

THE *Botanical Gazette* (Indianapolis) for September and October is chiefly occupied by a report of the papers read in the Botanical Section of the American Association for the Advancement of Science at its Ann Arbor meeting. These furnish satisfactory evidence of the good work doing in this branch of science on the American continent, and will not suffer from comparison with a similar record at any of the recent meetings of our own Association. The following are the titles of the papers read:—J. C. Arthur, proof that Bacteria are the direct cause of the disease in trees known as pear-blight.—C. R. Barnes, the process of fertilisation in *Campanula americana.*—C. E. Bessey, the question of bi-sexuality in the Zygnemaceæ.—C. E. Bessey, further observations on the adventitious inflorescence of *Cuscuta glomerata.*—T. J. Burrill, the mechanical injury to trees by cold.—D. H. Campbell, the development of the prothallia of ferns.—J. M. Coulter, on the appearance of the relation of ovary and perianth in the development of dicotyledons.—W. G. Farlow, notes on some injurious fungi of California.—E. L. Sturtevant, an observation on the hybridisation and cross-fertilisation of plants.—E. L. Sturtevant, germination studies.—As far as these papers are reported here, we may note Mr. Arthur's, Mr. Barnes's, Mr. Campbell's, and Mr. Coulter's as giving especially good evidence of a capacity for original work. Another interesting feature of this number is the report of the proceedings of the "Botanical Club," which held daily meetings during the session of the Association, with an attendance in all of no less than eighty-five members.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 19.—"On Variations in the Amount and Distribution of Fat in the Liver-Cells of the Frog." By J. N. Langley, M.A., F.R.S., Lecturer on Histology in the University of Cambridge.

The fat in the liver-cells is at its maximum amount in February and March. In April it rapidly decreases; from May until December it is present in comparatively small though varying amount.

Generally speaking, the fat globules form an inner zone in frogs which have hungered more than a week. In January, February, and March, however, the fat-globules are commonly more numerous in the outer part of the cells, often forming a distinct outer zone.

In December, when the fat in the liver is increasing in amount, cold increases the amount of fat stored up, and warmth decreases it.

The increase of fat, consequent on a decrease of temperature, occurs chiefly in the outer part of the cells.

The decrease of fat, consequent on increase of temperature, occurs chiefly or wholly at the outer part of the cells; as a rule, the number of globules in the inner part of the cells is increased.

Variations of temperature have much greater effect on the amount of fat in the liver in winter than in summer.

The ratio of fat formed to fat metabolised, depends in part upon certain unknown conditions of the body, independent of temperature or of food.

When frogs are fed, *e.g.* with worms, the fat in the liver at first decreases; after some hours it begins to increase, and becomes greater than at the beginning of digestion; towards the end of digestion it decreases again in amount, so that in one or two days the amount is normal. Whilst the fat is decreasing in amount, the globules usually decrease in size; whilst the fat is increasing in amount, the globules usually increase in size, and are found in the outer region of the cells. Later, as the fat returns to normal, the globules form more and more an inner zone.

Probably the metabolism as well as the formation of fat is more rapid in the outer than in the inner cell-region; and probably also there is in certain circumstances a transference of fat-globules from the outer to the inner part of the cells.

Each separate fat-globule appears to be slowly metabolised in the same way that mesostate granules in secretory glands are metabolised.

From June to August, peptone or dextrin, when injected into the dorsal lymph-sac of a frog, produces changes like those produced by feeding.

Mathematical Society, December 10.—J. W. L. Glaisher, F.R.S., President, in the chair.—Mr. A. E. Haynes, Hillsdale College, Michigan, was elected a Member.—The following communications were made:—On the numerical solution of cubic equations, by G. Heppel.—On a theorem in kinematics, by J. Y. Walker, F.R.S.—Note on the induction of electric currents in an infinite plane current sheet which is rotating in a field of magnetic force, by A. B. Basset.

Chemical Society, November 19.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following papers were read:—Aluminium alcohols; part 3, aluminium ortho-cresylate and its products of decomposition by heat, by J. H. Gladstone, F.R.S., and Alfred Tribe.—Notes on the constitution of hydrated and double salts, by Spencer U. Pickering.—Some new vanadium compounds, by J. T. Brierly.—On the action of PCl_5 upon ethylic diethylacetoacetate, by J. W. James.—On the vapour-pressures of mercury, by W. Ramsay, Ph.D., and Sydney Young, D.Sc. After criticising Regnault's determinations of the vapour-pressures of mercury, the authors show that his results do not agree with the following generalisation, which has been proved to be true in twenty-two instances. A relation exists between the absolute temperatures of all bodies, whether solid or liquid, whether stable or dissociable, which may be expressed in the case of any two bodies by the equation

$$R' = R + c(t' - t).$$

where R is the ratio of the absolute temperatures of the two bodies corresponding to any vapour-pressure, the same for both; R' is the ratio at any other pressure, again the same for both; c is a constant which may equal 0, or a small plus or minus number; and t' and t are the temperatures, absolute or Centigrade, of one of the bodies corresponding to the two vapour-pressures. When $c = 0$, $R' = R$, or the ratio of the absolute temperatures is a constant at all pressures; and when $c > 0$ or $c < 0$, its values may readily be determined either by calculation, or graphically by representing the absolute temperatures of one of the two bodies as ordinates, and the ratios of the absolute temperatures at pressures corresponding to the absolute temperatures of that body as abscissæ. It is found in all cases that points representing the relation of the ratio of the absolute temperatures of the two bodies to the absolute temperatures of one of them lie in a straight line. From this it follows that if the vapour-pressures of any one substance are known throughout, it is sufficient to determine accurately the vapour-pressures of any other substance at any two temperatures, sufficiently far apart, in order to be able to construct its whole vapour-pressure curve. The vapour-pressures of mercury have accordingly been measured with the greatest care at the temperatures $222°\cdot15$ C., $270°\cdot3$, $280°\cdot2$, $447°$, and $448°$. On comparing the ratios of the absolute temperatures of mercury and water, at pressures corresponding to those temperatures, they are found to agree with the equation $R' = R + c(t - t')$, where $c = 0\cdot0004788$, if the temperatures of mercury be chosen as ordinates. It is therefore possible to construct the complete vapour-pressure curve of mercury; the paper contains tabular statements of the values.

Linnean Society, December 3.—Sir J. Lubbock, Bart., President, in the chair.—Sir H. E. Maxwell, Bart., Lieut.-Col. L. Blathwayt, and Messrs. R. A. Bastow, S. J. Capper, C. Ford, G. B. Howes, J. H. Gurney, jun., W. H. Jones, W. F. A. Lambert, C. T. Musson, W. D. G. Osborne, D. Petrie, and G. Thom were elected Fellows.—The President announced from the chair, and there were read letters from (1) the Elizabeth Thompson Science Fund, U.S.A.; (2) Prix de Candolle; (3) Medals and money prizes of Roy. Soc. N.S. Wales.—The Secretary exhibited for M. Buysman a preparation of the floral parts of *Aconitum Napellus*, L.—Mr. V. I. Chamberlain exhibited and made remarks on a specimen of trap-door spider and nest from California.—D. C. Cogswell showed oil-paintings of *Eugenia jambos* and *Casparea porrecta* from Bermuda.—The Rev. G. Henslow read a contribution to the study of the relative effects of different parts of the solar spectrum on the transpiration of plants. His conclusions are: that his experiments prove that Wiesner's results are correct, and that transpiration *per se* (theoretically distinct from the purely physical process of evaporation, which takes place from all moist surfaces and bodies, dead or alive) is especially, if not solely, referable to those particular bands of light which are absorbed by chlorophyll, and that such light, being arrested, is converted into heat, which then raises the temperature within the tissues and causes the loss of water. The only additional results advanced tentatively are, that yellow light has a *retarding influence* upon transpiration, and that "life" has a retarding influence upon evaporation as distinct from transpiration.—Prof. T. S. Cobbold's notes on parasites collected by the late Charles Darwin was next read. This contains a letter from Mr. Darwin when transmitting the author the specimens in 1869, followed by Dr. Cobbold's own memoranda concerning eight of them, only one, however, *Distoma incerta*, proving new.—A paper was read, on *Castilloa elastica*, Cerv., and some allied plants, by Sir J. D. Hooker. The author states that under the name *Castilloa elastica* probably more than one species exists. The true plant first described by Cervantes has flowered and fruited in Ceylon; it is now fully described and figured, with remarks on allied plants also yielding Panama india-rubber. Seeds collected by Mr. Cross in 1875 failed to germinate, but cuttings were also introduced, and from them plants were distributed to various colonies. Some difficulty is found in propagating by cuttings, as the side branches, which are deciduous, will not strike root, but seedlings have now been raised at Peradenyia, and the culture is therefore assured. An account of the introduction of the plant is appended.—A paper was read by Mr. P. H. Carpenter, on the variations in the form of the cirri in certain Comatulæ. The shape and number of the cirrus-joints of *Antedon phalangium* vary so greatly, both in the same individual and in individuals from different localities, that, if the two extreme forms were met with in an isolated condition, they would assuredly be referred to different species of *Antedon*. The cirri of this species are classed by the author under four types:—(A) long-jointed, (B) intermediate, (C) square-jointed, (D) short-jointed. A is the typical form which occurs in the Mediterranean variety, but is also found in the Atlantic specimens, together with B, and also, but more rarely, C; while D is confined to individuals from the Minch and the Ross-shire coast, occurring together with C, which is rare in examples from the Atlantic, except in those dredged by the *Dacia* on the Seine bank.—The Secretary summarised a paper, by Mr. Joseph Baly, on the Colombian species of the genus Diabrotica, and in which the author divides the genus into two sections, dependent on the lengths of the second and third joints of the antennæ.

Zoological Society, December 1.—Prof. W. H. Flower, V.P.R.S., President, in the chair.—Mr. F. Day exhibited and made remarks on a very curious fish, supposed to be a hybrid between the Dab (*Pleuronectes limanda*) and the Flounder (*P. flesus*).—Mr. Sclater laid on the table specimens of some rare birds sent for exhibition by Mr. Whitely, of Woolwich, and called special attention to a Hornbill which seemed to prove that *Buceros casuarinus*, described by Mr. G. R. Gray in 1871 from the head only, was merely the young stage of *Bycanistes cylindricus*.—Mr. E. Lort Phillips exhibited a fine series of heads of antelopes obtained during his recent expedition to Somali-land in company with Messrs. James, and read notes on their habits and localities.—Mr. W. T. Blanford exhibited, on behalf of Capt. C. S. Cumberland, the head of a wild sheep from Ladak, supposed to be a hybrid between *Ovis hodgsoni* and *Ovis vignei*.—Mr. John Bland Sutton read a paper on the origin of the urinary bladder, in which he endeavoured to show that the atrophy of the gills in all forms of the vertebrates above the amphibians might possibly be explained by the assumption of embryonic respiration by the allantois.—A communication was read from Lieut.-Col. Swinhoe, containing the fourth part of his memoir on the Lepidoptera of Bombay and the Deccan. The present paper concluded his description of the Heterocera; and also contained descriptions of the Tortricidæ and Tineina, which had been worked out by Lord Walsingham.—A communication was read from Dr. R. W. Shufeldt, containing a memoir on the comparative osteology of the Trochilidæ, Caprimulgidæ, and Cypselidæ. Dr. Shufeldt came to the conclusion that the Trochilidæ should form an order by themselves, and were not nearly related to the Cypselidæ, which were only much modified Passeres.—Mr. F. E. Beddard read the second of his series of notes on the Isopoda collected during the voyage of H.M.S. *Challenger*. In the present paper the author treated of specimens referable to the family Munnopsidæ.—A communication was read from Mr. Martin Jacoby, containing descriptions of some new species and a new genus of Phytophagous Coleoptera.

Physical Society, November 28.—Prof. F. Guthrie, President, in the chair.—Mr. T. H. Blakesley was elected a Member of the Society.—The following communications were read:—On the calibration of galvanometers by a constant current, by Mr. T. Mather. A current is passed through the coils of a galvanometer, which may be of any form; the galvanometer is turned in a horizontal plane through any angle, which need not be recorded, and the deflection θ of the needle noted. The current is then broken, and the needle swings back, taking up its position in the magnetic meridian; the angle through which it turns to do this is also noted δ. This is repeated with the galvanometer in various positions and with the same current, and a curve is drawn showing the relation between the values of $\frac{\sin\theta}{\sin\delta}$ and corresponding values of θ. When the instrument is now used in its normal position it is readily seen that a current producing a deflection θ of the needle is proportional to the value of $\frac{\sin\theta}{\sin\delta}$ corresponding to θ, obtained in the calibration experiment which may be read off at once from the curve.—On a machine for the solution of cubic equations, by Mr. H. H. Cunyngham. This machine the author believes to be the only one hitherto constructed that gives the imaginary as well as the real roots of a cubic equation. A cubical parabola is drawn upon paper, the ordinates being the cube roots of the corresponding abscissæ. To find the roots of a cubic, first reduce it by Cardan's rule to the form $x^3 - Ax - B = 0$. Then measure off along Ox, a distance equal to B, and from this point, T, draw a line making an angle equal to $\cot^{-1}A$ with Ox. The ordinates of the points where this line cuts the curve are the roots of the equation. To find the imaginary roots when they exist, first find the real root as before; from this point draw a tangent to the branch of the curve the other side of Oy, then if this line cut the axis of x at a point Q, and α be the real root, the two imaginary roots are

$$\frac{\alpha}{2} \pm i\sqrt{\frac{QT}{\alpha}}.$$

Instead of actually going through the construction as above, the operation is preferably performed by applying a protractor with a tangent scale to the curve with its centre at T, setting it, and leading off the point of the curve cut by its edge.—On a machine for the solution of equations, by Mr. C. V. Boys. After mentioning Mr. Hinton's apparatus, lately shown to the Society, and briefly describing Mr. Kempe's equation-machine, Mr. Boys explained a machine he had constructed, consisting of a system of beams, each provided with a pair of pans, and working upon a fulcrum at the middle. The pans of the first beam are marked $+a$ and $-a$, those of the second $-b$ and $+b$, the next $+c$ and $-c$, and so on. Into these, weights equal in value to the coefficients a, b, c, &c., of an equation $a + bx + cx^2 + \ldots = 0$ are to be placed. A sliding joint is arranged to connect a point opposite the positive pan of each beam, with a rib at the back of the next lower one. Alternate beams are placed opposite one another, and each set can be slid past the other, the peculiar connecting-joints being able to slide past the fulcra and the pans on each beam. To solve an equation, the coefficient weights are placed in their pans, and the two sets of beams are made to slide past one another. At certain positions the beams change the direction of inclination. These positions of balance are noted on a scale, the readings of which are roots of the equation. When there are not more than two impossible roots, the machine will find them; for this purpose the real roots are first found and divided out, the resulting quadratic being placed on the machine. Instead of a change of inclination of the beam, a maximum or minimum of pressure is observed by a spring balance. The reading of the scale is then the real part of the root, and the square root of the pressure the impossible part.—Mr. A. Hilger exhibited and described a new driving clockwork of isochronous motion regulated by a fan-governor, and a new direct-vision spectroscope.

Geological Society, November 8.—Prof. T. G. Bonney, F.R.S., President, in the chair.—Henry M. Ami and R. Mountford Deeley were elected as Fellows of the Society.—The following communications were read:—Results of recent researches in some bone-caves in North Wales (Fynnon Beuno and Cae Gwyn), by Henry Hicks, F.R.S., with notes on the animal remains by W. Davies, F.G.S., of the British Museum (Nat. History). This paper contained the results of researches carried on in these caverns in the summers of 1883, 1884, and 1885 by Mr. E. Bouverie Luxmoore, of St. Asaph, and the author. The enormous collection of bones belonging to the now extinct animals of Pleistocene age obtained had been submitted for examination to Mr. W. Davies, and afterwards distributed to various museums. Several well-worked flint implements were also discovered in association with the bones. The following are the conclusions arrived at by the author, from the facts obtained during the explorations:—That abundant evidence has been furnished to show that the caverns had been occupied by hyænas, and possibly by other beasts of prey, as dens, into which portions of carcasses of various animals had been conveyed in Pleistocene times. The very great abundance of some animals, such as the rhinoceros, horse, and reindeer, and the frequent presence of bones belonging to young animals, proved that the plain of the Vale of Clwyd, with that extending northward under the Irish Sea, must have formed a favourite feeding-ground even at that time. The flint implements and worked bones showed also that man was contemporary with these animals. The facts perhaps, however, of greatest importance, made out during these researches, are those which bear on some questions of physical geology in regard to this area, which hitherto have been shrouded more or less in doubt. The views on the physical conditions in Pleistocene times of the areas in North Wales in which these and the other bone-caverns occur, so ably put forward by Sir A. Ramsay, appeared to the author to be strongly supported by the results obtained in these explorations. The ravine in which the caverns occur must have been scooped out previous to the deposition in it of the glacial sands and boulder-clays. This sand and clay, there seems good evidence to show, must have filled up the ravine to a height above the entrances to the caverns, and such sands and clays are now found at some points to completely fill up the caverns. How, then, did these sands and clays get into the caverns? Were they forced in through the entrances by marine action or by a glacier filling the valley? Or were they conveyed in subsequent to the deposition of the boulder-clay in the valley and surrounding area? The position of the caverns in an escarpment of limestone, at the end of a ridge of these rocks, with a sharp fall on either side, prohibits the idea that the material could have been washed in from the higher ground, as has been suggested by some in the case of other caverns, if it had anything like its present configuration. Moreover, there is scarcely any deposit now visible upon the limestone ridge, and there is no certainty that there ever was deposited there any great thickness of such a clay as that now found in the caverns. The general position also of the bones in some of the tunnels seems to indicate clearly that the force which broke up the stalagmite floor, in some places 10 to 12 inches thick, and stalactites 6 to 8 inches across, which thrust many of the large and heavy bones into fissures high up in the caverns and placed them at all angles in the deposit, must have acted from the entrance inwards, and the only force which seems to meet these conditions is marine action. The following seem to the author to be the changes indicated by the deposits. The lowest in the caverns, consisting almost entirely of local materials, must have been introduced by a river which flowed in the valley at a very much higher level than does the little stream at present. Gradually, as the valley was being excavated, and the caverns were above the reach of floods, hyænas and other beasts of prey occupied them, and conveyed the remains of other animals into them. Man also must have been present at some part of this period. Gradually the land became depressed, the animals disappeared, stalagmite was formed, and the sea at last entered the caverns, filling them up with sands and pebbles, and burying also the remains not washed out. Floating ice deposited in this sea the fragments of rocks derived from northern sources, and these became mixed with local rocks and clays brought down from surrounding areas. The greater part of the boulder-clay in the Vale of Clwyd was probably deposited as the land was being raised out of this Mid-Glacial sea. During the process of elevation the caverns became again disturbed by marine action and the upper fine reddish loam and the laminated clays were deposited. It seemed to the author impossible to avoid the conclusion that these caverns must have been submerged, and afterwards elevated to their present height of about 400 feet above the level of the sea, since they were occupied by Palæolithic man and the Pleistocene animals.—On the occurrence of the Crocodilian genus *Tomistoma* in the Miocene of the Maltese Islands, by R. Lydekker, F.G.S.—Description of the cranium of a new species of *Erinaceus* from the Upper Miocene of Œningen, by R. Lydekker, F.G.S.

Anthropological Institute, Nov. 24.—Mr. Francis Galton, F.R.S., President, in the chair.—The election of W. Seton Karr, E. Lawrence, Dr. R. Munro, and Dr. W. Summerhays, was announced.—Mr. C. H. Read exhibited a number of ethnological objects from Terra del Fuego.—The President exhibited on behalf of Dr. J. E. Billings, of the United States Army, a collection of composite photographs of skulls. There were in all twenty photographs, forming four series, referring respectively to Sandwich Islanders, Ancient Californians, Arapahoe Indians, and Witchitaw Indians; each composite was the mean of six adult male skulls.—Dr. Edward B. Tylor exhibited some Australian Tunduns or bull-roarers, and explained the manner in which they were used.—Mr. J. Theodore Bent read a paper on insular Greek customs, in which he described many ceremonies now used by the Christian inhabitants of the islands of the Ægean Sea that were obviously derived from, or survivals of, ancient Pagan customs. Mrs. Bent exhibited a collection of Greek dresses, drapery, and other objects from the islands referred to in the paper.—Mr. J. W. Crombie read a paper on the game of hop scotch, in which he traced the origin of the game to a period anterior to the introduction of Christianity, and showed that in early Christian times children had some rough idea of representing in this game the progress of the soul through the future world, and that the division of the figure into seven courts was on account of the belief in seven heavens.—Dr. E. B. Tylor gave a *résumé* of a paper by Mr. A. W. Howitt, on the migrations of the Kurnai ancestors (Gippsland).

Royal Microscopical Society, November 11.—Rev. Dr. Dallinger, F.R.S., President, in the chair.—The President referred in feeling terms to the death of Dr. W. B. Carpenter, C.B., a Fellow, and formerly President, of the Society, and a resolution of condolence with his family was passed. Prof. Stewart was appointed to represent the Society at the funeral.—Mr. Beck exhibited a portable form of his "Star" microscope, and Mr. Crisp exhibited a microscope with focussing adjustment by means of a piece of catgut, which, it was claimed, gave a very simple and easy motion.—Mr. J. Mayall, jun., exhibited the Helot-Trouvé electric photophore, which had been recommended as an excellent illuminant for microscopical purposes.—Mr. Groves exhibited a Barrett microtome, a very large form, intended for cutting sections of exceptional size.—Mr. Dowdeswell exhibited a cholera bacillus showing a flagellum at either end, one straight and the other coiled.—Mr. Nelson exhibited a very fine image of *Triceratium septangulatum*, showing markings in the areolation with a $\frac{2}{3}$-inch objective, and the low aperture of 0·29.—Mr. Badcock described an unknown fresh-water organism, closely resembling a Polycystin. The President suggested that it might possibly be one of the various forms of *Actinophrys*.—A paper was read by Mr. W. B. Turner, describing some new and rare Desmids; also one, by Dr. Giltay of Holland, on the proper mode of describing the amplifying power of a lens or objective.—Mr. Crisp read a paper on the limits of resolution in the microscope, in which he showed that whilst the limit with white light might be taken at 146,543 lines to the inch, the use of monochromatic light gave an increase to 158,845, and with photography to 193,037.—A paper was read by Dr. Lavis on preparing sections of pumice and other vesicular rocks.—It was announced that Mr. Mayall, jun., was about to give a course of five lectures on the microscope at the Society of Arts, illustrated by microscopes from the Society, and from Mr. Crisp's extensive collection.

Mineralogical Society, December 8.—L. Fletcher, M.A., President, in the chair.—The following papers were read:—On a glaucophane eclogite from the Val d'Aoste, by the Rev. Prof. Bonney, F.R.S.—Note on orthoclase from Kilima-njaro, by H. A. Miers, M.A.—Preliminary notice of penetration twins of arragonite from New Mexico, by R. H. Solly, F.G.S.—On some specimens of idocrase and garnet from the neighbourhood of Tzermatt, by Prof. W. J. Lewis.—Dr. Burghardt exhibited some pseudomorphs of native copper after arragonite, from South America.—Mr. Miers also exhibited some peculiar twins of calcite from Eyam, Derbyshire.

Entomological Society, December 2.—Mr. J. W. Dunning, Vice-President, in the chair.—Two new Fellows were elected.—Mr. F. Enock described experiments in mounting *Mymaridæ*, and exhibited photographs of the insects.—Mr. A. Eland Shaw exhibited an undetermined species of *Conicephalus*, which had been taken in a hothouse at Birmingham; it was believed to be an Australian or South American species.—Mr. G. T. Porritt exhibited two species of a melanic variety of *Ayrotis obelisca* from Sligo.—Mr. Dunning read a note on the election of honorary foreign members.

Victoria Institute, December 7.—A paper on the unreasonableness of agnosticism was read. The author treated the subject in such a manner as to make his essay specially valuable at this time.—Mr. E. Charlesworth read a paper on the skull of the gorilla, of which he exhibited a specimen considered the most perfect that had as yet reached England.

CAMBRIDGE

Philosophical Society, November 23.—Prof. Foster, President, in the chair.—The following communications were made:—On a new method of producing the fringes of interference, by L. R. Wilberforce, B.A. The author stated that in the course of an inquiry into the suitability of various forms of interference-fringes for certain investigations on the velocity of light upon which he had been engaged, he had been led to adopt the mode of production which was the subject of his paper. He briefly described the method, indicated the elements of its theory, and, by a comparison of his results with those of former experimenters, showed the great increase of accuracy attainable by means of it.—On the dielectric strength of mixtures of gases, by Dr. C. Olearski. The author described a series of experiments from which it followed that the dielectric strength of a mechanical mixture of two gases is intermediate between the strengths of its constituents.—On the mutual action of oscillatory twists in a vibrating medium, by A. H. Leahy, M.A.—On the transpiration stream in cut branches, by F. Darwin, M.A., and R. W. Phillips, B.A. The paper consists chiefly of an experimental criticism of Dufour's experiments on transpiration. The authors show that (contrary to Dufour's contention) there is an essential similarity between the natural current of water in a transpiring branch, and the current induced by pressure in a similar specimen; this similarity being understood to hold good under the conditions of Dufour's experiments, namely, when certain incisions are made, or when the branch is compressed in certain ways.

PARIS

Academy of Sciences, December 7.—M. Jurien de la Gravière, Vice-President, in the chair.—Determination of the differences of longitude between Paris, Milan, and Nice, by MM. F. Perrier and L. Bassot. The values obtained for the differences of longitude between the observatories of these places is found to be:—

Milan–Paris ...	+27m. 25·315s.		
Paris–Nice ...	−19m. 51·513s.	27m. 25·325s.	Δ=0·01s.
Nice–Milan ...	− 7m. 33·812s.		

—Movement of the molecules of the so-called "solitary wave" propagated on the surface of a stagnant canal, and which after some agitation acquires a constant and uniform motion, by M. de Saint-Venant.—Experimental researches undertaken to determine the influence exercised by lesions of the spinal marrow on the form of the convulsions assumed by artificial epilepsy of cerebral origin, by M. Vulpian.—On the theory of algebraic forms in connection with M. Halphen's differential invariants, by M. Sylvester.—Note on the fresh experiments carried out in 1885 with the navigable balloon *La France*, by M. Ch. Renard. The results of three ascents during the months of August and September gave a mean velocity of about 6·7 metres per second, with 55 to 57 revolutions of the screw per minute. On the two last occasions the balloon was brought back to the point of departure, Chalais, near Meudon.—On the propagation of motion in an undefined fluid (1st part), by M. Hugoniot.—Discovery of a new comet in the constellation Andromeda at the Paris Observatory on December 1, by M. Fabry.—Observations made at the Observatories of Paris, Bordeaux, Lyons, and Algiers, presented by M. Mouchez.—On the employment of spherical convex glasses (boules-panorama) as solar signals, by M. Hatt.—Note on certain hyper-Fuchsian functions, by M. E. Picard.—On Lagrange's form of interpolation, by M. Bendisson.—Note on the trigonometric series, by M. H. Poincaré.—On the solutions common to several partially-derived linear equations, by M. R. Liouville.—On the holomorphous conditions of the integrals of the iterative equation, and on some other functional equations, by M. G. Kœnigs.—Remarks relative to a preceding communication on M. Kœnig's theorem, by M. Ph. Gilbert.—On the part played by the rotation of the earth in determining the deviation of running waters on the surface of the globe, by M. Fontes. The author considers it now demonstrated that terrestrial rotation has a perceptible influence on the tendency shown by rivers to corrode one side or the other of their banks.—Note on the spectrum of absorption of oxygen, by M. N. Egoroff. The results of the author's spectroscopic researches, combined with those of M. Thollon, completely explain the origin of the telluric bands in the section A—*b* of the solar spectrum; 126 bands, distributed in equal proportion and identically in the groups A, B, and α, depend exclusively on oxygen, while the others belong to the vapour of water.—On the characteristic equation of carbonic acid, by M. E. Sarrau.—On the preparation of hypophosphoric acid, by M. A. Joly.—Note on some properties of zinc, by M. L. L'Hôte. Pure zinc, alloyed with a very small quantity of arsenic or antimony, conducts itself in water like zinc alloyed with iron. Hence all the zincs of commerce decompose water at the boiling-point.—Heat of combustion of some ethers of organic acids: ethylic ether of lactic acid, citrate of ethyle, normal ethylbutyric ether, ethylisobutyric ether, by M. Louguinine.—On the pyrogenous decomposition of the polyatomic acids of the fatty series, by M. Hauriot.—On the normal and primary monochlorurretted butyric compounds, by M. Louis Henry.—Action of chlorine on anhydrous chloral, by M. Henri Gautier.—Analysis of the deposits formed by the mineral waters of Chabetout, Puy-de-Dôme, by M. Fr. Thabuis. The chief constituents of the deposits from these ferruginous waters are sesquioxide of iron, nearly 50 per cent.; organic matter, 9·4; lime, 2·2; gelatinous silica, 11·1; carbonic acid, 1·8.—Optical examination of some little-known minerals: kirwanite, a silicate of the protoxide of iron, lime, and alumina, with about 4 per cent. of water; hullite, consisting mainly of amorphous matter, and found in the Irish basaltic rocks; harringtonite, a zeolithe of lime and soda; bowlingite, a hydrosilicate of alumina, iron, and magnesia; botryolite, identical with datholite, by M. A. Lacroix.—On experimental denutrition, by M. Ch. E. Quinquand. This process, which consists in *starving* an organ, or part of an organ, supplies a new and useful method of investigation, enabling physiologists to advance the study of elementary nutrition and of the fundamental action of medicines.—On the effects produced by the ingestion and intra-venous injection of some colouring substances derived from coal, and much used in colouring drinks and aliments, by MM. P. Cazeneuve and R. Lépine. One of these (binitronaphthol, or Manchester yellow), is shown to be distinctly injurious; the other two derived from it quite harmless.—On the anatomy, digestive, and nervous systems of the genus Discina, by M. L. Joubin.—Account of a young megaptera recently stranded in the maritime district of La Seyne (Mediterranean), where this species of whale is extremely rare, by M. G. Pouchet.—On the respiration of plants, continued, by MM. G. Bonnier and L. Mangin.—On the desiccation of plants immersed in aqueous solutions, by M. Albert Levallois.—On the processes of fructification of the various genera of sigillaria, by M. B. Renault.—On the underlying rocks of the Tertiary formations in the neighbourhood of Issoire, Auvergne, by MM. Michel Lévy and Munier-Chalmas.—Geological observations on the kingdom of Shoa and Galla country, south of Abyssinia, by M. Aubry.—Note on the discovery of phosphates of lime made in the spring of the present year in the lowest Tertiary strata in the south of Tunis, by M. Philippe Thomas.—On the Jebel Zaghwan range, Tunis, and on the great fault in this orographic system running north-east and south-west, and indicating the line of upheaval of the lower chalk formations now in contact with the Upper Eocene rocks, by M. G. Rolland.—Note on the discovery of a human station dating from the Stone Age in the woods of Clemert, by M. Emile Rivière.—On the advantages to be derived from a thorough knowledge of the displacements of the Gulf Stream in weather forecastings, by M. de Tastes.—Various communications on the shooting stars of November 27, from M. Stephan, of the Marseilles Observatory; M. Hirn, of Colmar; M. Colladon, of Geneva; M. Perrotin, of Nice; M. Quenin, of Pelonne (Drôme); MM. Hildebrandsson and Charlier, of Upsala; M. Phipson, of London; and others, with remarks by M. Faye.

THE LOAD-LINES OF SHIPS

THE regulation of the depth of loading of ships is a matter that has received the attention of scientific men and practical seamen during many years. It has been hotly discussed in various quarters, and numerous disputes have arisen over the attempts of the Board of Trade to carry their views respecting it into practice. A long series of debates and disputes culminated in the appointment of a Committee by Mr. Chamberlain, the late President of the Board of Trade, to report upon the question.

That Committee, now well known as the late Load-line Committee, had Sir E. J. Reed, K.C.B., M.P., for its Chairman, and reported to the President of the Board of Trade in August last. The Report was unanimous; and was conclusive as to the practicability of framing general rules concerning freeboard which will prevent dangerous overloading without unduly interfering with trade. The Committee's rules have been accepted by the Board of Trade and Lloyd's Register Society; and at the same time they have received the general approval of ship-owners.

Like many answers that are given to questions, the Committee's Report states the opinions that were arrived at, but does not give the reasons for them. This natural omission has been supplied by a paper read before the Society of Arts on the 11th inst., by Prof. Elgar, of Glasgow University, who was a member of the Committee. Prof. Elgar said:—

"It is necessary to understand the causes of the differences between the various types of vessels. It must be obvious that no simple rule of a given number of inches per foot of depth of hold, can now be applied with equal fairness to all vessels alike. Each requires to be judged of separately, and to have its special characteristics adequately appreciated. The problem of framing a general scheme for regulating the freeboards of the principal types of ships involves, firstly, the consideration of how freeboards should vary in vessels belonging to any given type, according to size, proportions, and form; and, secondly, the consideration of how the freeboards of vessels of similar sizes, proportions, and forms, but of different types, should be regulated relatively to each other."

He went on to show how the elements of size and relative proportions are dealt with in the Committee's tables, and also how form is taken into consideration by means of approximate coefficients of fineness.

The effects of differences in sheer and round of beam are separately investigated, and also the influence of deck-erections—such as forecastles, poops, midship houses, and others—upon seaworthiness. The whole question of allowances for deck-erections of various kinds is one which cannot be brought within the scope of exact different treatment; and it is a point upon which the Committee appear to have been guided more by the opinions of seamen and by the recorded experience of successful ship-owners than by any other considerations.

Among the chief scientific questions connected with the safe loading of ships are those of structural strength and stability. Prof. Elgar describes as follows the manner in which these have been treated by the Load-line Committee:—

"Flush-decked steamers of the 100 A class in Lloyd's Register, which are of full strength to the upper deck, are, it is known, amply strong enough to bear loading to the freeboards given in the tables. Spar and awning deck-vessels, which are of less strength, may become unseaworthy through excessive straining action at sea if loaded to the same depths as the vessels above-named. And there are instances of vessels of those types having been severely strained at sea, and of some which have probably foundered in consequence, when loaded unduly deep. The principle which the Committee has adopted in dealing with these and other vessels that are inferior in strength to those of the 100 A class of full scantling ships in Lloyd's Register, is to fix approximately the limits at which the stress upon the material of the hull shall not exceed that of the stronger class of the same proportions, form, and moulded depth, when loaded to the freeboard required by the tables. In our present state of knowledge of how to calculate exactly the relative stresses upon the materials of ship's hulls, it is impossible to rely upon absolute accuracy of comparison, but the principle is a sound one. It can be applied with a fair degree of accuracy in many cases, and it is only to be expected that the present deficiencies in this branch of science will be made good in time. In thus adopting Lloyd's 100 A class as a standard of strength, the Committee must not be supposed to indorse Lloyd's Rules in any sense. They are merely taken by the Committee as being the best, or, indeed, the only recognised standard we now have.

"The question of stability is one that has often been raised in connection with the regulation of freeboards. Stability is, however, so intimately associated with stowage that it is only possible to deal with it by defining how ships of various proportions and types are to be stowed. The Load-line Committee did not feel called upon to deal with an independent problem of such magnitude and such great complexity as this. Stability need not ordinarily enter into the determination of the load-line, except for the purpose of insuring to ships of great proportionate depth the necessary stability at sea when employed in the carriage of grain, or other cargoes that are approximately homogeneous. If properly qualified persons are intrusted with the assignment of load-lines, they will readily distinguish between vessels in which stability is likely to be a question of importance and those in which it is not. In cases where vessels will obviously admit of being loaded so as to become unstable at sea, the owners should be looked to for particulars of the stability, and for furnishing proof that, so far as stability is concerned, the vessel may be safely laden with her intended cargoes to the load-line given in the tables, or to such a reduced draught as may be considered proper. The responsibility of providing stability, or of showing that sufficient is provided, must be left with ship-owners. Stability is regulated by stowage; and no mere provision of freeboard, height of platform, or strength of structure, can make a ship safe if her stability is not secured by proper stowage. The regulation of stowage has but little more to do with freeboard tables than has the regulation of steam-power, bulkhead division, manning, and other essential elements of safety. Each of these points requires to be separately and fully dealt with."

Great importance is rightly attached by the Load-line Committee to the administration of the freeboard tables. The most perfect tables that can be framed must necessarily be incomplete in many particulars, and must leave much to the discretion of those who have to use them. The mere tables only apply to existing types of vessels; and out of those existing types they can only apply to vessels of high class which are in good condition. In the administration of the tables great discretion and knowledge are necessary, in order to use them with reasonable modifications, in view of changes in the types of ships, or of improvements in ships, that the continuous progress of naval architecture is certain before long to cause. The same discretion and knowledge are necessary in dealing with vessels which, by reason of age, structural defects, more or less rapid deterioration, or of anything that may be observed in their condition, cannot safely or fairly be loaded as deeply as vessels which are in first-class condition. The great majority of the members of the Committee are of opinion that, in order to give useful and satisfactory effect to the tables, the scientific staff of the Board of Trade should be strengthened, and should be made capable of dealing with all questions of such a nature that may arise, in a manner likely to command the confidence of ship-owners and of the public. They also think it essential that this work should be done under the superintendence of a representative body, which should consist not only of officials but also of ship-owners, naval architects, seamen, and perhaps underwriters.

Sir E. J. Reed said, "The Load-line Committee, in the inquiry which they undertook, had a very difficult task to perform. The origin of that Committee was this: the Legislature having placed the obligation of stopping the overloading of ships on the Board of Trade, that Department tried to do so, but failed to succeed, their interference being resisted by ship-owners. Thereupon Mr. Chamberlain conceived the idea of forming a Committee of gentlemen for the purpose of thoroughly investigating the subject, and seeing what answers could be given to the questions which had been referred to in the paper. The best proof that the Committee had done its work with a fair measure of success was to be found in the fact that no one had that evening complained of the results at which they arrived, which would not have been the case had mistakes been committed, as ship-owners never hesitated to defend themselves. Prof. Elgar had shown how necessary it was to supplement the labours of the Committee by further knowledge and investigation touching other elements of the safety of ships at sea. He believed ship-owners came out exceedingly well in the inquiry, both in the evidence they laid before the Committee and in the manner in which they applied their knowledge and experience to the investigation; and he should feel it his duty, when he saw Mr. Chamberlain, to point out to him that nothing could have been more fair-minded, more open or thorough, than the manner in which they co-operated with the other members of the Committee in bringing about the result which had been attained."

The public are indebted to the Load-line Committee for the satisfactory manner in which they performed a most difficult task; and especially to the Chairman, Sir E. J. Reed, to whose ability and good judgment the success of their labours may very largely be attributed.

THE WANDERINGS OF PLANTS AND ANIMALS

The Wanderings of Plants and Animals from their First Home. By Victor Hehn. Edited by James Steven Stallybrass. (London: Swan Sonnenschein and Co., 1885.)

THE title of this book is somewhat misleading, since it treats only of domesticated animals and cultivated plants, and of these solely in relation to European civilisation. The subject is treated as almost entirely a philological one, the origin of the several species and varieties being deduced from a study of their names in different countries and from a critical examination of the earliest references to them in ancient writers. The author's point of view is thus clearly stated in the preface:—

"The purely scientific man will judge chiefly by the suitability of soil and climate. If he finds a plant flourishing pretty abundantly in Greece or Italy now, and knows of no climatic or geologic changes that would exclude its having flourished there 5000 years ago, he will at once pronounce it indigenous, and scout the notion of its having been imported. But now listen to the scholar, and he may tell you that Homer never mentions such a plant; that later poets speak of it in a vague way as something very choice and very holy, and always in connection with some particular deity: they may have tasted its fruit, may have seen the figure of its flowers (probably conventional) in emblematic painting or carving, but have not the faintest notion of its shape or size, whether it be a grass, a shrub, or a tree; till at last, in the time of Darius or Alexander, the plant itself emerges into clear visibility. Your inference will be that it came to Greece within historic times."

In this way he claims to have shown "that the flora of Southern Europe has been revolutionised under the hand of man; that the evergreen vegetation of Italy and Greece is not indigenous, but is mainly due to the sacred groves planted round the temples of Oriental gods and goddesses; that in this way the laurel has followed the worship of Apollo, the cypress and myrtle that of Aphrodite, the olive that of Athena, and so on." But this very wide statement seems hardly to be justified by the evidence adduced in this volume.

As a good example of our author's mode of treatment we may refer to his account of the domestic cat. This animal, he shows, was quite unknown to the Greeks and Romans of the classical age. In the Batrachomyomachia the mouse tells the frog that he fears above all things the hawk and the weasel, but most the weasel, because it creeps after him into his holes. In "The Wasps" of Aristophanes a domestic story begins: "Once upon a time there was a mouse and a weasel"—just as we say to children, "There was once a cat and a mouse." In the fable of the City mouse and the Country mouse as related by Horace, the latter is frightened, not by a cat, but by the barking of dogs. In the original fables of Æsop, of Babrius, and of Phædrus, the cat is never mentioned, the weasel always occupying the place the former animal now fills in the house. No remains of cats have been found in Pompeii, though the bones of horses, dogs, and goats have been discovered, and some writers have imputed this to the superior intelligence and foresight of the former animal, which made its escape in time, whereas its absence is due to the fact that there were no cats in the city at the period of its destruction.

The cat was first domesticated in Egypt, and appears to have been introduced into Europe in the fifth or sixth century of the Christian era. It is first mentioned under its distinctive name, *Catus*, by Palladius, and somewhat later by the ecclesiastical historian, Evagrius Scholasticus. The author believes that the introduction of the cat followed the migration of the rat, *Mus rattus*, from Asia into Europe, where it seems to have been altogether unknown in classical times.

As an illustration from the vegetable kingdom we may take the discussion on the origin of the eatable chestnut. The name is traced to Asia Minor, and that it was not indigenous to Europe is shown by the fact "that neither Greeks nor Romans had an individual name for the chestnut-tree and its fruit." It is further argued that, "If the Greeks had found the chestnut-tree existing in their future country when they first arrived, they would certainly have mentioned the fruit in their legends. But we only hear of the acorns of the *drus*, the esculent oak; and the aborigines, such as the wild Arcadians in their mountains and woods, are always called *acorn-eaters*, even by the oracles. When Hesiod describes the blessings of peace and justice, the earth bringing forth fruits, the oak bearing acorns, the bees furnishing honey, and the sheep yielding its fleece—would he have forgotten to mention the chestnut, if it had then grown on the mountains, bestowing sweet fruit on mankind? And would the Latin poets, when describing the Golden Age, have limited themselves to mentioning arbutus-fruit, strawberries, cornel-berries, blackberries, and acorns? That the regions south of the Caucasus, and the northern seaboard of Asia Minor, bring forth all kinds of nuts and chestnuts in great abundance, is proved by the unanimous testimony of travellers, ancient and modern. . . . From these regions chestnuts came overland through Thrace, Macedonia, and Thessaly to Eubœa, after which island they were called Eubœan nuts at Athens."

The chief faults of this book are due to the want of any acquaintance with systematic natural history on the part of either author or editor. This has led to many errors of nomenclature and a most confusing arrangement of subjects. Beginning with a chapter on the horse, we pass on to the vine, fig, and olive, and then back to asses and mules. Then comes "stone architecture," followed by "beer" and "butter." After a number of vegetables, trees, fruits, and flowers are discussed, we come to fowls, pigeons, and other domestic birds; then more fruit-trees; then the cat and the buffalo, followed by the hop and grain-bearing plants. As illustrations of the want of some technical knowledge of natural history we have the prickly *Ruscus aculeatus*, instead of the glossy-leaved *Ruscus racemosus*, given as the Alexandrian laurel; the *cytisus* of the ancients, a shrub used extensively as fodder for cattle, and rightly identified as the *Medicago arborea*, confounded with the laburnum, an ornamental tree of a totally different character. The Virginian creeper (*Ampelopsis hederacea*) is confounded with another American plant, the fox-grape (*Vitis labrusca*), while the Lombardy poplar, a native of Western Asia, is said to have been brought from the Mississipi Valley.

Being evidently quite unacquainted with the discoveries of Darwin, the author greatly exaggerates the changes produced by man in the flora of Europe, considering it to offer a parallel case to that of St. Helena, where the indigenous vegetation has been almost wholly extirpated and replaced by plants from other countries. The incapacity of archaic insular forms to compete with the dominant races developed in the great continents is supposed to obtain equally in a portion of one of these ancient continental areas; and thus, the extensive development of certain useful or ornamental cultivated plants in Southern Europe is mistaken for the substitution of a new flora of a totally distinct type. That this is his belief is shown by the following passage:—

"Almost everything that strikes the northern traveller on crossing the Alps as novel and agreeable—the quiet plastic beauty of the vegetation, the characteristic forms of the landscape and animals, nay even the geological structure (in so far as it has become exposed by changes in its organic covering, and has then felt the effects of light and atmospheric agencies)—is a product of civilisation brought about by manifest transformations during long periods of time."

Notwithstanding a few blemishes such as those now indicated, the student of philology and of the early history of domesticated animals and cultivated plants will find this volume full of curious information; while there is so much discursive matter touching upon the primitive history of nations, their manners and customs, their arts and literature, and even their religion and philosophy, that the book will be interesting to a wide circle of general readers.

ALFRED R. WALLACE

EUROPEAN BUTTERFLIES

European Butterflies. By W. F. de Vismes Kane, M.A., M.R.I.A., Memb.Ent.Soc.Lond., &c. 8vo. Pp. i.-xxxi., and 1-184, with plates. (London: Macmillan and Co. 1885.)

IT has long been a standing reproach to British entomologists that they are mainly divided into two classes, those who collect or study British insects only, and those who, with little knowledge of the productions of their own country, are profound regarding exotics. In other words, continental Europe is a blank to the majority of them. And the purely "British" entomologist, as a rule, is supposed to look upon anything continental as unclean; yet nevertheless prizes any unusual species if captured on our shores, and uses every argument to prove that it may possibly be a true native, and not an immigrant, for if the latter there must be a certaint taint attached to it. The "purely British" entomologist is also supposed to endeavour to maintain his conservative ideas by refusing to enter into correspondence and interchange with his continental brethren, because everything not British is unclean. He retains a peculiar method in the preparation of his materials that renders them not only practically useless for purposes of study, but prevents them from being serviceable if by any chance they should fall into the hands of "foreigners." The writer has often been compelled to hear and to bear very strong expressions from his continental friends on this point. The writer has a book on *Lepidoptera* before him, and as nine-tenths of "British" entomologists confine their attention to *Lepidoptera*, the term "British entomologist" is here used in its narrow sense.

The time *will* arrive when we can safely say "*Nous avons changé tout cela.*" According to what we have observed during an experience of nearly thirty years, it is in rapid progress towards arrival, and that progress has been vastly accelerated recently. Many of our entomologists are expanding their ideas by continental travel, and latterly we have had from their pens several important indications that it is possible for British entomologists to know something about the productions of continental Europe, and even to endeavour to teach and lead their fellow-countrymen in the same direction. The thin end of the wedge naturally consists in popularising the subject.

The thin end of the wedge has been inserted, and it is being driven deeper to an extent that must create alarm amongst "British" collectors. There was a time when they had a nomenclature almost their own, and resented any attempt to upset it. Even this pet has been rudely insulted in the eyes of the most conservative in their number.

We have said that nine-tenths of our entomologists are probably Lepidopterists. The most attractive *Lepidoptera* are butterflies, and it is in this direction that the thin end of the wedge is being specially inserted. Almost within a year three works by British writers concerning European (as including British and continental) *Lepidoptera* have made their appearance. There are Lang's "Butterflies of Europe," and a re-issue of Kirby's "European Butterflies and Moths." Now we have before us Kane's "Handbook of European Butterflies." We welcome all as constituting the thin end of the wedge.

Mr. Kane's book differs in its plan from the works mentioned in connection with it. The only parallel to be drawn is with Kirby's "Manual," published nearly twenty-five years ago. Mr. Kane has produced a portable book that can, and should, go into the pocket of every entomological tourist. With no disparagement of the praiseworthy attempts of other writers to insert the thin end of the wedge, we incline to think this work will give it a sharper edge. So far as any work of the kind can be called a "handbook," this seems to be to the point. It is limited to the butterflies of Europe (geographically). The arrangement is that of Staudinger. The plan is to give concise descriptions of each species (in which abbreviations are freely, but intelligibly, used), notes on habits if known, and a copious list of localities; the latter is especially full for Switzerland, the south of France, and the Pyrenees, but wants enlarging for some other countries. When following Staudinger, the author should not have committed the error of wrongly designating *Papilio podalirius;* he overlooked the fact that Staudinger thought proper to correct himself in this case. It is not for us to compare the abbreviated descriptions with the insects; they bear the impress of being good. The introductory remarks are well considered: the endeavours to differentiate a butterfly from a moth might well have been modified; the distinctions have become so subtle as to rest more on intuition than anything else. Our author judiciously advocates the practice of placing the captured specimens in *papillottes* in the first instance, and fully explains the process. He does not appear to have remembered a suggestion by Dr. Jordan, to the effect that when the collector is *en voyage* a dozen specimens of the smaller butterflies may be placed in a pill-box, and both time and space be thereby economised (this would not answer in the case of exotic collectors). Our author evidently writes from personal experience, and is enthusiastic in his description of some of his excursions. His enthusiasm even carries him too far, for when he says: "Such days as these rise upon the memory like a reminiscence of Paradise, fraught with glories of colour, odour, light, and life," we are tempted to marvel why he again became mortal! The plates form almost a new departure in the method of illustrating works of this kind. There are 15, on which are about 130 figures. They are adapted from a peculiar photographic process. We have seen other attempts in this direction. Nothing can exceed the beauty and faithfulness of some of the figures in Mr. Kane's book; and here arises the difficulty: they are unequal, and so we fear will remain all attempts to apply photography where particular colours or shades are involved.

The author is responsible for the remarks on "preparation" that here precede the notice of the book itself. He avows himself personally in favour of setting his specimens flat (justly complaining of the imperfections of some of the pins used on the Continent), but advocates only half measures—a comparatively short pin on which the insect is to be set "half-way." This is a decided advance, and the practice is now often followed for British insects by the less conservative; but English pins (of the required length and not open to the objections stated) can be had, and on them the insects should be set in the continental fashion. Or continental pins would do equally well if used of a stronger size than is often done. The stronger the pin (up to a certain point) the more durable the specimen. The subject of pinning and preparation was thought not unworthy of forming the substance of the address of a recent President of the Entomological Society. Whether it was appreciated or not we cannot say, but if (as we believe was so) the writer of that address sought to destroy one of the greatest barriers that exists between British Lepidopterists (always excluding the thoroughly conservative irreconcilables) and scientific fraternity with the rest of the world, the subject was worthy of the occasion. R. McLachlan

ANALYTICAL GEOMETRY

A Treatise on the Analytical Geometry of the Point, Line, Circle, and Conic Sections, containing an Account of its most recent Extensions; with numerous Examples. By J. Casey, F.R.S. (Dublin: Hodges, 1885.)

Dr. Casey, by the publication of this third treatise, has quite fulfilled the expectations we had formed when we stated, some months since, that he was engaged upon its compilation. It is a worthy companion of those which have preceded it. It possesses many points of novelty, *i.e.* for the English mathematician. He has, from the first introduction of certain recent Continental discoveries in geometry, taken a warm interest in them, and in the purely geometrical treatment of them has himself given several beautiful proofs, and has added discoveries of his own, as we have already pointed out in our notice of the last edition of his "Sequel." We may here note that this last work has met with a very warm welcome in France and Belgium. The author himself has added so much in years now long past to several branches of the subject treated of in the volume under notice—the equation of the circle (and of the conic) touching three circles (three conics), and other properties—that he is specially fitted, by his intimate acquaintance with it and by his long tuitional experience, to write a book on analytical geometry.

The divisions are into eight chapters, the first of which, in four sections, treats of the Point, three sections being taken up with Cartesian and polar co-ordinates and the transformation of co-ordinates; the fourth section gives a brief account of Complex Variables, introduced by Cauchy in 1825, and extended by Gauss: "the introduction of these variables is one of the greatest strides ever made in mathematics." The second chapter, on the Right Line, treats it (§ 1) by Cartesian, then (§ 2) by trilinear, and (§ 3) by point and line co-ordinates; this last comparison is taken from Clebsch's "Vorlesungen der Geometrie." In Chapter III. four sections are devoted to the circle, § 2 being devoted to a system of tangential circles, § 3 to the "trilinear" forms of equations to the old circles and to all the recent circles; § 4 is devoted to tangential equations. Chapters IV., V., VI., VII. treat of, respectively, the general equation of the second degree, the parabola, ellipse, and hyperbola. Chapter VIII. (miscellaneous investigations) discusses many matters of novelty and interest: § 1 is on contact of conic sections; § 2, similar figures, gives a good *résumé* of results connected with Brocard's points and circles, Neuberg's circles, M'Cay's circles, and Kiepert's hyperbola (if upon the three sides of a triangle ABC similar isosceles triangles be described, the triangle formed by their vertices is in perspective with ABC, and the *locus* of their centre of perspective is an equilateral hyperbola); in § 3, on the general equation in trilinear co-ordinates, Aronhold's notation is "now published for the first time in an English treatise on conic sections"; the remaining six sections are occupied respectively with Envelopes, Projection, Sections of a Cone, Homographic Division, Reciprocal Polars, and Invariants and Covariants. An idea has now, we trust, been conveyed to the reader of the ground covered by Dr. Casey: a good deal of it is, of course, well-worn ground, but even this has been adorned by his touch, and much relating to the new circles has never before been introduced into our books. These circles must soon become as familar to our junior students as the nine-point circle, whose properties are by this time nearly exhausted.

The examples are exceedingly numerous, and a good feature is that most of the results obtained in them are numbered consecutively with the important results of the text: this enables the author to refer to them with facility. They exceed 600 in number.

There are several minor typographical inaccuracies which are easily corrected, but there are besides incorrect references to back articles and pages, which cause the reader some little annoyance in using the book: these can be easily rectified in a second edition (one on p. 150 gave us trouble, for Art. 23 read 21, p. 33).

It remains only to say that the expenses of the publication have been defrayed by the liberality of the Committee of the "Dublin University Press Series."

TWO YEARS IN THE JUNGLE

Two Years in the Jungle: the Experiences of a Hunter and Naturalist in India, Ceylon, the Malay Peninsula, and Borneo. By William T. Hornaday, Chief Taxidermist, U.S. National Museum, late Collector for Ward's Natural Science Establishment. (London: Kegan Paul, Trench, and Co., 1885.)

THE author of this somewhat ponderous volume was sent to India by "Professor" Ward, the well-known purveyor of natural history specimens at Rochester, New York, for the purpose of collecting various zoological desiderata, and especially skins and skeletons of the larger mammalia, and of crocodiles. The importance of this kind of collecting is greater than would be supposed by those who have no experience of its difficulty, and the task of securing specimens, and of preserving them so as to render them useful for scientific study, demands no inconsiderable amount of courage, perseverance, and knowledge. The majority of the skins and skeletons of the larger mammalia in European museums are derived from the specimens, generally dwarfed in stature, and very often diseased, obtained from menageries, and if these are to be replaced by the spoils of wild individuals, hunters who have a considerable knowledge of taxidermy must be engaged to collect. Many of the largest and most remarkable mammalia of the world are being rapidly exterminated, and before they share the fate of the dodo and *Rhytina* it is to be hoped that good skeletons, at all events, may be rescued for the study of future generations.

Mr. Hornaday is evidently an enthusiast in his art, and having greatly enjoyed both the sport of shooting wild animals and the process of converting elephants, tigers, orang-utans, crocodiles, and other formidable denizens of forest and swamp into useful museum specimens, he proceeds in the present work to give a full account of his wanderings and adventures during two years and nine months, the greater portion of which was spent in very wild parts of South-Eastern Asia and some of the neighbouring islands.

On the whole, and despite many shortcomings, both literary and scientific, the book is an agreeable account of an interesting journey, and scattered through the volume are many useful zoological notes. Amongst the most important of these are those referring to orang-utans, of which Mr. Hornaday obtained forty-three specimens, the majority shot by himself. He gives a series of measurements, which are particularly useful, of these and of several of the other mammalia which he obtained. He also describes the "nests," or rather resting-places, made by orangs, though the figure which he gives of one is unfortunately taken from an artificial imitation set up by him in the Museum at Washington and not from nature. The figure in question looks more like a gigantic crow's nest than the rough platform described at p. 403, and does not agree with the description. The curious proboscis monkey, *Semnopithecus* (*Nasalis*) *larvatus*, the Bornean gibbon, and several Indian and Ceylonese monkeys also furnish occasion for interesting notes, some of which are novel.

The greater part of the work is however devoted to descriptions of shooting wild animals, such as may be found in dozens of sporting books, or to accounts of the ordinary incidents of travel, and the book is prolonged by dissertations on the habits of animals, and on specific characters. Here the author is fairly beyond his depth. Chapter XX., for instance, is occupied with an account of the habits of the Indian elephant. Nearly the whole is compiled from Sanderson and other writers, and some of the statements thus copied are of very doubtful accuracy. Thus Schlegel's view that the Ceylon elephant is the same as the Sumatran, and distinguished from that of India by the number of ribs and dorsal vertebræ—a view long since shown by Falconer to be untenable—is stated as if it were an undoubted fact. Before, however, one has read much of Mr. Hornaday's work, it is manifest that the author's zoological knowledge is superficial and imperfect. At p. 14 the limestone of which the pyramids are built is said to be "full of nummulites, little flat echinoderms;" and at p. 72 we read, "unlike all other antelopes, the female gazelle possesses horns." Of course the author meant to write, unlike all other *female* antelopes, but this does not prevent the statement being a gross error; it might have been expected that any one writing on mammalia would be acquainted with such conspicuous instances of horned female antelopes as are offered by the eland and oryx.

It may naturally be inferred that the scientific names applied to animals by Mr. Hornaday are not always correct. For instance, at p. 107 he records the shooting in the Wynaad forest, Southern India, of a specimen of *Semnopithecus leucoprymnus*, a kind of monkey peculiar to Ceylon. The animal shot was probably *S. priamus*, of which there is a fine South Indian specimen in the Agassiz Museum, Cambridge, Mass., very possibly derived from Mr. Hornaday's collection, but wrongly labelled *S. entellus*. The circumstance that the Wynaad *Semnopithecus* is wrongly identified makes it probable that the Ceylon monkeys called *S. leucoprymnus* (pp. 268 and 277) were also *S. priamus*.

One point in Mr. Hornaday's favour it is only just to notice. His account, so far as it is possible to judge, is truthful. He may err in citing authorities who are incorrect, but his own observations appear trustworthy, and he records his failures with as much spirit as his successes. The illustrations are numerous and as a rule fairly good, if not always very artistic, but some of the views, and especially that of Ootacamund, opposite p. 96, give a poor, and not a very correct idea of the scenery.

W. T. B.

OUR BOOK SHELF

Traité de Zoologie Médicale. Par Prof. R. Blanchard. Part I. (Paris: J. R. Baillière et fils, 1886.)

IT is difficult to comprehend what is meant by medical zoology, but it is easy to take in the object and design of this manual. These are to give a general sketch of the structure and classification of the various forms of animal life, and to call the attention in some detail of medical men or students to those species, which are either useful or injurious to man. It would thus aim at combining an introduction to zoology with a short treatise on animal parasites and some notes on economic zoology. We doubt if in the pages of a small volume such a treatment of this vast subject could be satisfactorily carried out, and it speaks a great deal for the knowledge and tact of Prof. R. Blanchard, that he has, so far as we can judge from this first part of his manual, succeeded in producing a most readable work, which cannot fail of being attractive to the class for whom it has been written, and the knowledge conveyed in which is fairly up to a modern point of view. The manual is destined to form a volume of about 800 pages, illustrated by some 400 figures, which, for the most part drawn from original sources, are fairly reproduced. We note that at least in one case this reference to original figures has not been without its advantages, for the figures given by Saville Kent, in his manual of the Infusoria, of *Asthmatos ciliaris*, Salisbury, not being exact, have been misleading to others who have again reproduced them, and there can be no doubt that this so-called parasite, thought to be the cause of hay catarrh, is nothing but an isolated epithelial cell of the naso-pharyngeal passages. The references to authorities seem very complete, and the second part is promised immediately with a title-page and "les tables." May we hope that these latter will include an index of the species referred to, or at least of those the life-histories of which are given in detail. This would immensely increase the usefulness of the volume.

Microskopische Reactionen. By Dr. Haushofer, Professor am Technischen Hochschule, Munchen. (Braunsweig: Vieweg und Sohn, 1885.)

THIS book will be hailed both by the ordinary chemist, and also by the geologist, and also by the pharmacist, as a most valuable addition to our already very numerous books on chemical reactions or analysis. The object of the author has been to arrange in such a form as can be used in the laboratory, tests and reactions of a great number of substances which may be performed on very minute quantities, and the resulting bodies recognised by their characteristic forms under the microscope. As the author says, some substances are so easily recognised in minute quantities even in the ordinary way, like iron, iodine, or by spectroscopic means, as thallium or lithium, that recourse to the microscope is seldom necessary. But in the majority of cases, where small quantities have to be looked for, the style and general habitus of crystal produced either in precipitates or by evaporation from solutions, and especially their behaviour towards polarised light, gives most valuable indications of the presence of any metal, and where, as in most cases can easily be done, several salts are in this way compared, the results are quite as conclusive as with large quantities. The substances treated of are metals, non-metals, and acids, which are arranged for greater convenience of reference in working, in alphabetical order. The principal and most general forms of crystals are illustrated by 137 well-executed woodcuts.

A Bibliography of Protozoa, Sponges, Cœlenterata, and Worms; including also the Polyzoa, Brachiopoda, and Tunicata, for the Years 1861-83. By D'Arcy W. Thompson, B.A., Professor of Biology, University College, Dundee. (Cambridge: The University Press, 1885.)

THE importance of the well-known "Bibliotheca Zoologica" of Engelmann, with its immense and accurately-compiled supplement by Victor Carus, to the biological student need not be insisted on, and in the present work we have this record carried out to 1883 for the large groups of the Protozoa, Sponges, Cœlenterata, and Worms, including also the Polyzoa, Brachiopoda, and Tunicata. This volume of nearly 500 pages has been beautifully printed at the Cambridge University Press, and is one that will be a most handy work of reference to all students. In a short preface the author apologises in advance for possible deficiencies. It would be impossible to have a work of this sort free from omissions; but we have gone over very carefully the portion of the bibliography with which we were most familiar, and have been very much struck with its extreme accuracy. It is proposed to publish in the course of 1886 a supplement, to contain all detected omissions, and the author will gratefully receive any additional titles that may be sent to him. We would suggest that it might not add too much to the labour of preparing this, and that it would certainly add to the value of the supplement if omissions in Carus's volumes were also taken notice of, so that the bibliography of the groups now catalogued by Mr. D'Arcy Thompson should be fairly complete. This has been, we notice, already done in some instances in the volume before us. An index of authors' names would also be of use.

On the Ethics of Naturalism. (Shaw Fellowship Lectures, 1884). By W. R. Sorley, M.A. (W. Blackwood and Sons, 1885.)

THE theory of evolution has established its claim to having given the most satisfactory account of all forms of natural life, and Mr. Sorley endeavours here to show how it yields, by advancing it a step further, a complete explanation of human nature, mental as well as physical.

Whence, then, do human rules of action and aspirations for future right conduct come, and what sustains them? Mr. Sorley points out that happiness cannot *explain* the definite end of human action; it is only another name for it. Education and legislation combine to make the greatest happiness of the greatest number the desirable thing for each man's actions to tend towards, but there is little difficulty in pointing out the weakness of the theories of earlier writers who have tried, without the help of Darwin, Spencer, Galton, and others, to explain the feeling of duty; the feeling that we *ought* to do one thing rather than another when the former does not at the time seem so agreeable. We may quote Hobbes, for instance, who is unable to explain why any man feels any *duty* to his neighbour, and invents the fiction of the 'social contract"; and Prof. Bain, who has to account, by the associations of a few years, for the harmony of feeling between the individual and the whole. Evolution, of course, explains that although in the earlier days of the human race, each beneficial action sprang from egoistic motives, yet that the good result to the society has led to an inherited sympathy with such actions and such actors. There is the difficulty that since present ideas, according to the doctrine of evolution, are the latest outcome of all past experience, and what we are is the last result of all past influences, we seem to arrive at the very unprogressive conclusion that whatever is is right. And if, indeed, each man found that he had arrived at perfect harmony with all his surroundings, this would be the ideal state. This, however, is the case with none of us. Few of us but find the well-known utterances of the former and the "Video meliora, proboque, deteriora sequor" of the latter the counterpart of our own experiences, and still more easy is it to see how far from the present accepted ideals are all our neighbours. But as among all the slightly differing variations of a species there is a tendency to return to one type, so among all the contending inclinations and dispositions of the members of a race there abides an inherited code of morality, now become instinctive; one, as nearly fixed in each individual as the form of any species, but, like that, varying and developing in different individuals, families, and nations, and adapting itself to changed surroundings. These surroundings have always in human history been so different that the inborn or ideal code has not at any time become a general, still less a universal, one, and the struggles after holiness of the Hebrew, after beauty of the Greek, and after justice of the Roman, are still being continued in various proportions as modern times and conditions of existence have altered.

To some a morality never to be fixed will not appear a very steady one; a morality that is calculated to vary at different epochs and in different climates. Yet, surroundings always changing, man has to adapt himself to the change; always, therefore, will he be labouring towards a changed goal. Neither is it a cheerful prospect for the race. There will always be the "necessity for strong egoistic feelings and conduct in the struggle for existence, where the better-equipped organism asserts and maintains its supremacy only by vanquishing the organisms which are not so supplied." This struggle will continue on the highest levels of progress to which our race will reach; for "the multiplication of desires and of desiring individuals keeps so well in advance of the means of satisfying desires, that it is doubtful whether the course of evolution is fitted to bring about complete harmony between different individuals. It would almost seem that the 'moving equilibrium' in human conduct in which there is no clash of diverse interests cannot be expected to be brought about much before the time when the physical factors of the universe have reached the stage in which evolution ends."

Clark's Transit Tables for 1886. (London: E. and F. N. Spon, 1885.)

MR. LATIMER CLARK is still faithful to his self-imposed duty of enabling any one to obtain accurate time in any part of the world by means of the transit instrument, without any calculation. As in former years, Mr. Latimer Clark has now computed from the *Nautical Almanac* all the data necessary to enable this to be done for 1886. The author is doing a good work, for which every student of astronomy should thank him, for we have little doubt that most of those who procure a little transit instrument, and work it under Mr. Clark's able direction, will not end there.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Late Total Eclipse

ALLOW me to call the attention of such of your readers as are not already aware of the fact that the phenomena I mentioned in my notes of the late eclipse—the "pulsation" of the sun's light just before totality and the simultaneous "wave-shadows"—are recorded by Grant ("Hist. of Phys. Astronomy," p. 404) as having been witnessed in France during the total eclipse of 1842. He mentions several probable causes or contributing causes; among them the unsteadiness of the air, which certainly existed here. I have not been able to find these phenomena (or phenomenon with a double aspect) mentioned in any other work accessible to me, and should be obliged to you for a statement of the explanation now received. To an outsider the (apparent) rarity and local character of the phenomenon seem to cause this difficulty:—If it is owing to any cosmical cause, or one common to any large part of our atmosphere, it would seem that the phenomenon should be more widely seen; if, on the other hand, it is owing to the unsteadiness of the observer's atmosphere, should it not occur oftener?

Allow me to add that in suggesting in my notes that the small prominences I saw were "Baily's Beads" I was writing ignorantly, having been long under the impression that Baily's

Beads were a phenomenon of totality, and coloured; a reference to an elementary work showed me my error. What I saw was a row of small similar-looking and about equidistant prominences of a faint pink colour. A. S. ATKINSON

Nelson, N.Z., November 13

Brilliant Meteor

I CAN confirm Mr. M'Keague's statement regarding an extremely brilliant meteor observed by him on November 27, the train of which remained visible for fifteen minutes, for about 6 o'clock the same evening I saw, when near Edinburgh, the train of one very bright meteor (brighter than Venus) last for at least ten minutes. I did not time it exactly, but it could not have been less than that, and while it remained visible it kept curving round, and diffusing itself out into a thin cloud. About half an hour later I saw the train of another very bright one remaining and behaving similarly for about five minutes.

Broxburn, December 18 JOHN STEVENSON

Models Illustrative of Phyllotaxis

PROF. PARKER's note upon this subject induces me to mention a rough-and-ready contrivance, which I found serviceable when lecturing on this subject. This consisted merely of the framework of a collapsible opera-hat, or of two or three superposed. It is easy to attach stiff labels to these in any desired order, and easy to illustrate undeveloped or developed internodes, as the case may be. I have used the joints of an old telescope for similar purposes. Of course these are "makeshifts" only, but they are available when better things are not at hand. MAXWELL T. MASTERS

The Viper (*Vipera berus*, L.)

THE following letter, addressed to me by a most intelligent farmer, may be thought worthy of publication, as furnishing an additional item of evidence on a much-debated question.

"*Church Dale House, Egton, Grosmont, Yorkshire,*
November 10, 1885

"DEAR SIR,—In the beginning of the harvest of 1878 or 1879 I was with my late father, Mr. Thomas Stanforth, of Howlsike, near Lealholm, North Yorkshire, in a corn-field on the Howlsike Farm, when we noticed a large viper in a rough part of the field. My father exclaimed, 'Hold on, there's a hagg-worm,' and just at that moment the viper moved its head and hissed, when we both saw some ten or twelve young vipers glide into the mother's mouth. My father immediately crushed the head of the animal with his heel, and we laid it on a stone wall, intending to open it at our leisure. Proceeding to our work, this was forgotten, and I did not again see the viper until the following winter, when I found it still lying on the wall, but reduced to a skeleton. I examined it closely, and found many small perfect skeletons inside the larger one.

"In the summer of 1865 I saw a large viper opened, and a full-grown skylark taken out of its stomach.

"Yours truly,
(Signed) "ROBERT STANFORTH"

Much circumstantial evidence has already been printed on this alleged habit, and it is not unreasonable to suppose that the young reptiles, when disturbed, will rush into the nearest opening that presents the appearance of a place of refuge; but I do not remember to have seen any proof of the viper returning her young to liberty when the supposed danger was past. If they merely lodge in the gullet they can doubtless be ejected at will; if they pass into the stomach, their uneasy motions may act the part of an emetic, and produce nausea and vomiting before asphyxia sets in or digestion begins; and in either of these cases the action of the mother in permitting her brood to enter her mouth may be regarded as voluntary and instinctive. It is, however, possible that the young vipers may dart, uninvited, into the parent's mouth when it is opened in the act of hissing, and that they may quickly perish and be converted into food. We can only repeat the words of the late Prof. Bell, F.R.S., written thirty-six years ago:—"In this state of doubt upon so interesting a subject, it is perhaps better to await the results of direct experiment, which might be readily made in any locality where these reptiles abound" ("British Reptiles," 2nd edition, p. 69). R. MORTON MIDDLETON, Jun.

Castle Eden, December 10

Ventilation

MR. FLETCHER, of Warrington, ought to be an authority on such a matter as ventilation, and probably he has omitted in his letter to you some material points. I should like to know something of the supply of fresh air to the rooms where the ventilation failed. If that was abundant, then, it seems, there should have been an up-draught in each flue, though, as the current in the ventilating flues would have been less than in those of the chimneys, it would have been better if possible to have their outlets a little separate. If, however, the supply of air to the rooms were insufficient for the joint draught, then the ventilating flue (so called) would have become a down-cast shaft, and (owing to its situation) would have brought down smoke, &c., as described; and this insufficient supply, when the fires were lit and the ventilation shaft heated, might have been quite enough when there was no fire, or the chimney might have been the down-cast.

It has always seemed to me that this matter of air-supply is at the bottom of ventilation failures. The amount required is so large, that it must be warmed before entering a room in winter, but there are few houses where any provision is made for this. In fact, as matters stand, it seems to me that it would be nearly impossible to make satisfactory arrangements in most cases without great expense. No doubt the best arrangement would be to warm all the air, in one place, before entering the house, and to employ the fires or stoves in the rooms only to give locally greater warmth or brightness; but such an arrangement is so un-English that I suppose it must be rejected. Because our forefathers, when they first roofed themselves in, transferred their fire from the forest or cave to the middle of the hall, and then to the side with a chimney, we must follow the same practice; meanwhile closing up the inlets, which were plentiful enough in the early arrangement. We may be Radicals, but, like our ancestors, in most things, we do not wish to change the laws of England. J. F. TENNANT

37, Hamilton Road, Ealing, W., December 18

Snails Eating Whitening

I DO not know if the observation which is recorded below is new, but it is certainly new to me, and seems to be sufficiently interesting for publication. In the autumn of 1884 I noticed that the whitening which had been painted on some greenhouse glass in a garden at Reading, had evidently been eaten off by a large Gasteropod. The whitening was almost entirely removed from one pane, and partially from many others. The outlines of the parts which had been eaten were quite unmistakable, exactly resembling on a large scale the well-known traces left by freshwater snails on the conferva-covered glass of an aquarium. I did not find the snails at work, but the gardener assured me that he had seen them upon the glass, and that they were the common garden snails (*Helix aspersa*). Considering the entirely characteristic appearance of the marks, I think it may be taken as proved that the whitening was eaten by some large Gasteropod, and almost certainly by *Helix aspersa*. It is exceedingly probable that other forms of calcium carbonate (especially limestone rocks) are eaten in the same way, but the conditions of this particular form of the substance—spread out as it was in a thin film on a transparent layer—rendered the fact that it had been eaten especially conspicuous. As to the importance of calcium carbonate to the snail, it must be remembered that there is not only the necessity for growth of the shell in the young animal, and its repair in the adult; but there is also a regular periodical need in the latter for material to supply the place of the calcareous dart (*spicula amoris*), which is discharged before coitus, and is believed to act as an excitant in the sexual relations of these animals. The membrane (hibernaculum) which closes the mouth of the shell in winter is also to some extent calcareous.

December 14 EDWARD B. POULTON

Blackbird with White Feather

THERE is about my garden a hen blackbird with a white feather in the tail. I do not know whether this variation has been noticed before.

JOSEPH JOHN MURPHY

2, Osborne Park, Belfast, December 21

CYCLES

Variable Speed-gear

FIVE methods have been employed for making the speed of the wheels variable with respect to the pedal crank-axle whilst the tricycle is in motion, so as to vary the power to suit the nature of the road.

(1) A set of change wheels may be thrown in and out of action as desired.

(2) An epicyclic train may be used which for one speed is locked together and moves as a single piece, and is set in motion for the other speed. The well-known cryptodynamic two-speed-gearing was figured and described. In this an internally toothed wheel is keyed to the crank-axle. Connecting this and a loose pinion on the axle are four live pinions, the axles of which are attached to the chain-wheel. The internal wheel is fitted with a clutch, by which it can either be held stationary or keyed to the chain-wheel; when keyed to the latter the gear moves as one piece, and the higher speed is employed; when held stationary the live pinions roll round the centre wheel so that the chain-wheel travels less fast than the crank-axle, and then the greater power is obtained. This change can be effected by a striking lever.

(3) A third plan is to use two sets of chain-wheels and chains, either of which can be connected or disconnected at pleasure.

(4) Expanding chain-wheels can be used. Generally one only is employed and an idle pulley is provided for taking up the slack of the chain. A specimen was exhibited in which the pitch of the teeth is never altered.

(5) Another method of obtaining increased power is to use cranks with a variable throw. A diagram was shown of such a crank which could be changed in length by preventing it from rising by pressure when at the bottom of the throw; for at that time only is it free to turn on an eccentric, being locked by pawls and a gravitating bolt at any other position.

Position of Rider.—In every machine there is a certain position for the rider's seat, in respect both to the axle of the driving-wheel and to the crank-axle, which, on the level, will enable the rider to work to the greatest advantage. In ascending a hill the rider requires to be moved more forward, but he is in reality put further back, and the reverse is true when descending a hill. The most perfect contrivance for this purpose is the swing frame, which has been applied by Mr. Warner Jones to the Devon tricycle. The saddle and crank-axle are on the same frame, which is capable of rocking about the main axle and of being locked in various positions. By such means a rider is enabled to ascend a hill without leaning forward in the usual manner. A modification of the same arrangement by Mr. Griffiths was referred to.

Another method of varying the position depends on the use of a sliding base to the saddle-spring, which may be actuated by a lever and locked in one of three positions.

Hand-power Tricycles.—A few machines driven by the arms instead of by the legs have been made, but from the greater weakness of the arms they cannot compete with ordinary cycles, but are suitable only in special cases. Two machines, the Velociman and Oarsman were described. In the Velociman a pair of hand-levers are connected to the cranks of a second axle, which drives the main axle by a chain as usual, differential gear being employed to actuate the wheels. The rear steering-wheel is actuated by a lever carrying a cushion, which can be moved by inclining the body. In the Oarsman the action is similar to rowing. The rider sits on a sliding or a rocking seat, and pulls a cross-bar which is attached to a pair of driving ends which pass over pulleys connected with the driving wheels by clutches. During the return stroke the pulleys have their motion reversed by a spring.

[1] Continued from p. 135.

Sociable Tricycles.—Of tricycles for two riders those in which the riders sit side by side are called Sociables, and those in which one is in front of the other, Tandems. The Sociable is merely an enlargement of the single form with some part in duplicate. Some can be converted into a single machine. In the Coventry rotary Sociable, since four wheels are on the ground, a joint has to be introduced to allow for the inequalities of the surface. In this machine each rider drives the wheel on his side only. An ordinary front-steering pattern of convertible tricycle was figured, in which, when one wheel is removed from the single form a second half-frame can be bolted on, while the axle of the added part is fitted where the wheel was removed, and the crank-axle of the added part is bolted to the crank-axle of the single part; thus the two riders drive through the same chain the box of the differential gear which drives each wheel equally.

Tandem Tricycles.—In these there is more scope for variety, and the different machines may be classed as follows:—

(1) The ordinary front or rear-steering tricycle in which the wheel-base is extended, so that the riders may be seated fore and aft of the differential-geared driving-axle without destroying the balance of the machine.

(2) The Humber tandem, in which the extra rider is seated in front of the driving-axle, but as nearly over it as possible, and communicates motion to it in a similar manner to the rear rider, who is seated further back than in the single machine so as to counterbalance the extra weight in front.

(3) A machine in which an auxiliary trailing frame is fixed in the rear of an ordinary front-steering tricycle. In order that the trailing frame may rise and fall with the inequalities of the road, and may follow properly when the machine is running round a curve, it is necessary for it to have both a transverse and a vertical joint between the two frames. A figure was given of a trailing frame with a chain to drive its own wheel which could be clamped to the back of any front-steering tricycle. With this arrangement there is no necessity to take off a chain when detaching. A special detachable chain for convertible tandems was shown.

Carrier Tricycles.—The most useful kind of tricycle of all is that for carrying a burden. First the "Coventry Chair" was exhibited. This consists of a Bath-chair in which the large wheels are driven by a rider at the back in the same way as the wheels of a tricycle. The driver also controls the steering and manipulates the brake. The passenger sits in a comfortable wicker chair. Though these machines cannot be driven with the freedom of an ordinary tricycle, yet when their weight and the fact that there is a passenger on board is considered, they travel with marvellous ease. Examples of journeys made were given.

Of goods carriers there are a large number of makes, but there is nothing in their construction to call for special comment; their success depends chiefly on the load being balanced as much as possible on the driving wheels. They are largely used by the Post Office for the parcels post, for the delivery of letters in rural districts. They are also largely used by newspaper offices for the distribution of papers, and by tradesmen for the delivery of goods.

Arrangement of Driving Gear.—Tricycles driven by rotary action may be subdivided according as the differential gear-box is in the centre or on one side, and according as the driving chain is in the centre or on one side.

In side-driving tricycles the loop frame is generally employed and the gear-box may be either at the centre or the side.

In central-driving tricycles the frame is usually of the T pattern. Here again the gear-box may be either at the centre or the side. Theoretically there is an advantage in the central position of the gear-box, as the friction due to the bearings is equally distributed between the two wheels, whereas with side-gear one wheel only is retarded by this friction, but practically the difference is inappreciable. In central-driving machines the bearings must be so distributed as to prevent the main axle from bending under the pull of the driving-chain. The advantages of the T frame are its simplicity and lightness and the possibility of using adjustable cranks.

Width.—As the width of a tricycle varies between thirty-six and thirty-nine inches—excepting the Coventry Rotary, which from its special design can be made as narrow as twenty-seven inches—many arrangements have been devised for temporarily reducing the width, so as to enable a machine to pass through an ordinary doorway. Two plans only call for special notice, namely, folding frames and telescopic frames. A folding frame, when one or more pins are removed, can be folded up, but can still be wheeled along. In telescopic frames, which are always used with central-gearing, the frame and the axle on one side of the machine are made telescopic, so that by slackening a nut the parts slide over one another. A telescopic axle was shown.

Weight of Tricycle.—The proportionate weight of the several parts of a loop-frame front-steering tricycle were given.

Component Parts of Cycles

Of the component parts of modern cycles the following alone call for special notice: wheels, bearings, frame, steering-gear, brake and pedals.

Suspension wheels, the first great improvement in cycle construction, are made with either solid or hollow rims, the latter being the lightest and strongest. In an ordinary wheel the spokes are radial; they are threaded through holes in the rim, and screwed into the edge of the flanges of the hub, being butt-ended or enlarged where the thread is cut upon them. The section of the rims is crescent-shaped. Hollow rims are made either from a tube by rolling it to form, or out of a single strip of steel plate bent to the desired section, in which case the edges lap over one another and are brazed together; or out of two or more strips of metal bent to form and brazed or sweated together.

Round rubber tyres are used, but with surfaces sometimes corrugated longitudinally, which gives a better hold on the road. The outer surface of the tyres is sometimes made of harder rubber to diminish the wear, while the elasticity of the inner and softer rubber saves the jolting of hard rubber alone. Tyres are usually fixed by cement, which when properly done is sufficient, but a wire passing through the centre of the tyre is used by some.

Tangent spokes are employed to give extra torsional rigidity to the wheel. The spokes, instead of being radial leave the hub nearly at a tangent alternately in opposite directions; sometimes a single piece of wire is threaded through the flange and the two ends made fast to the rim by nuts, but in that case they invariably give way first at the point of the double bend. Headed spokes passing transversely through the edge of the flange are now used.

One of the latest innovations in the construction of wheels consists in corrugating the spokes throughout their entire length, which gives a certain amount of elasticity to the wheel. At first sight it would appear that these corrugations should seriously diminish the lateral stability of the wheel; but as far as experience shows such is not the case. As, however, wheels so constructed have not been very long in use, it remains to be seen whether they will stand the wear and tear of the road.

Bearings.—The bearings of the wheels are now almost without exception made with anti-friction balls interposed between the moving parts. The most approved kind is that known as the Æolus, which can be adjusted concentrically. The balls lie round a groove on a collar on the axle, on the two sides of which they bear. They are enclosed within a concentric casing composed of two pieces, one of which screws within the other. Each of these has a hollow conical surface, between which the balls are free to run. One piece can be screwed in until there is as little shake as may be desired, and it may then be locked in position by a small toothed bracket. A diagram was given showing the section of the usual small wheel bearing also capable of concentric adjustment. The results of the experiments made by Mr. Boys on the wear of balls in ball bearings were given. He found that in running 1000 miles each ball lost in weight only 1/250 grain, which is equal to an actual surface wear of only 1/158,000 inch.

Frame.—The frames of both bicycles and tricycles are largely constructed of weldless steel tube. In the bicycle the front fork is made of tube tapered and worked into an oval section so as to give the greatest possible strength to withstand the severe torsional stress to which it is subject. The back-bone is left round, but is tapered, while the hind-wheel forks are usually made from a stamping in sheet steel.

The hollow framing of tricycles is usually circular, having a diameter of from 1 to 1¼ in. and a thickness of from 0·065 to 0·095 inch. The large number of solid parts necessary are usually made from wrought-iron or steel stampings. Malleable-iron castings are also largely used and are the cause of many of the breakdowns of machines. Owing to the great expense of dies the temptation to use these is strong. This expense, combined with the fact that the patterns of tricycles at present are frequently being changed, is the cause of the present high price of first-class machines.

Steering-gear.—The steering-gear may be dealt with under two heads: (1) the method of mounting the steering-wheel so that it may be turned for the purpose of steering; (2) the method of controlling the wheel.

(1) The steering-wheel of all bicycles and of most tricycles is mounted in a fork, at the top of which is a "head" by which the fork is attached to the frame. In the head is the joint to allow the steering-wheel to be turned. The "Socket" and the "Stanley" head were described and a figure given of an improved "Stanley" head in which, instead of cones, balls are used to allow of free motion between the head and the central pin. A figure was given of another form of Stanley head in which a central pin is employed.

The steering-wheels of tricycles are not always mounted in forks. Among other methods that employed in the "Quadrant" tricycle was described, and another in which a large skeleton hub carries within it a small head actuated by a lever from the outside.

(2) On an ordinary bicycle the steering is controlled simply by a handle bar rigidly fixed to the fork.

Tricycles have their steering actuated usually by the rack and pinion; a handle-bar as used on a bicycle is also employed either connected directly with the fork or through levers.

Owing to the sensitiveness of this mode of steering, mechanism has been contrived which tends to keep the steering-wheel to a straight course. The most effectual is that employed on the Humber make of front-steering tricycle. A V-shaped cam on the steering-rod lies in a corresponding recess on the top of the socket of the steering-spindle and is held down by a spring. When the machine is steered the spring is compressed by the action of the cam, and so it tends to bring the wheel back to the straight line.

Brake.—There are but two varieties of brake; the spoon- and the band-brake. The spoon-brake consists of a spoon-shaped lever so pivoted that it can be pressed against the tyre of the large wheel in the bicycle or the two wheels of a tricycle.

The band-brake, almost exclusively used on tricycles, consists of a band of steel lined with leather encircling a drum in the driving-axle. By a hand-lever this can be tightened with great foree. In some central-geared tricycles a band-brake can be applied with the foot to the crank-axle.

Pedals.—When bicycle cranks are used the pedals are mounted on pedal pins bolted to the cranks. With cranked axles they are made in two halves. Ball bearings are frequently employed. Both rat-trap and rubber pedals are made: the latter are more slippery than the former, but absorb more vibration and so are more comfortable. The combination pedal with rat-trap plates on one side and rubber on the other is due to the author. A common cause of danger in bicycle riding is the slipping of the feet from the pedals when driving with much power, which puts the weight so far forward as to throw off the rider in front. Pedals to grip the feet have been devised, but some forms are apt to hold the feet so firmly as to make a sudden dismount occasionally impossible. The author has invented a pedal in which by bell-crank levers the foot is only held when pressure is exerted.

Fittings, &c.—Of the fittings and accessories the varieties are far too extensive for enumeration; but many display an amount of ingenuity that will well repay an inspection of them. The manufacture of these fittings forms separate trades, which employ a large amount of capital and labour.

The Chairman having complimented the author on the excellence of his paper, invited discussion.

Mr. C. Vernon Boys, referring to the undoubted going powers of the small Safeties, thought that in addition to the reason given in the paper the facts that the wind resistance was enormously reduced and that the rider could work in a position of comfort, without straining himself to ride as high a wheel as possible, had a great deal to do with the observed result. He thought that on a racing path the wind resistance of the spokes was the chief opposition to the motion of the machine.

He pointed out that the method of turning the Otto as described by the author, though employed by some, was essentially bad, tending to rub the tyres off one of the wheels, and explained the perfect method by which the wheels are made to turn simultaneously in opposite directions, by which no strain is put upon the tyres and only half the space is required for turning.

He thought too much preference had been given the clutch as compared with the differential gears for driving tricycles, and pointed out that in starting round a curve owing to the fact that the wrong wheel—the inner one—alone drives, more strain is thrown upon the steering-wheel, causing it to slip, than it ever experiences in ordinary riding when one wheel of a differentially-geared machine meets with greater resistance from mud or other causes than the other.

He mentioned the fact that Mr. Burstow, the inventor of the centre-cycle, had shown him nearly two years ago a double-acting clutch such as the author considered to be even more perfect than the differential gear, but he did not know how it was constructed.

Passing on to the Oarsman tricycle, Mr. Boys said that though apparently a hand-worked machine it was in reality driven chiefly by the muscles of the legs and body, and the stroke was only completed by the arms; and also that though a clutch-driven machine it had the advantages of a differentially-geared machine, in that when turning a corner the two cords could be pulled to different extents, and each wheel could at all times be driven.

He gave his experience of the elastic spokes. Since Christmas he had ridden a pair of wheels 3,800 miles, and had tested them most severely, but as yet they showed no signs of becoming untrue or losing their elasticity.

He had made further tests of the wear of balls, letting them run 1000 miles without being opened, after which he found that the wear was about one-fifth the rate of that previously observed. This, he considered, went to show that the wear, such as it was, was almost entirely due to a very small amount of grit which it is impossible to prevent from entering the bearing from the screw however carefully it may be cleaned. However, the result last obtained showed that the loss of weight of each ball in travelling 1,000 miles, during which it turned on its own axis about 1,400,000 times was less than 1/1000 grain. This, he thought, showed that those who found fault with ball bearings did so very rashly.

Mr. Sampson referred to a machine shown at the Inventions Exhibition on the lines of the Otto, but driven with a chain and with definite worm-gear for steering, which was worthy of attention.

Mr. Dalby, speaking as a rider, said he was sure that the author of the paper had not set the invention of the balance gear at its true value, that he had done special pleading on behalf of the clutch system. After severely criticising the arguments of the author, he attributed the poisibility of the modern tricycle mainly to the balance gear.

Mr. F. Warner Jones thought that more might have been said on the principles of cycle construction. The paper had been mainly descriptive of machines, and very little of first principles was to be found in it.

He agreed that the wind resistance was so much less felt on the small safeties than on a full-sized machine, that this should be considered an important factor in the cause of their good qualities. But he did not quite agree with Mr. Boys as to the way in which this acted. In any case the seat must be about seven inches behind the pedal axle to enable the rider to work in a proper position. With a saddle so placed on an ordinary bicycle the position became dangerous when descending a hill, but owing to the construction of the safety bicycles this position could be attained with perfect safety, the rider being more between the wheels. On a high machine the wind acted with a greater leverage, throwing more pressure on the hind-wheel in proportion than in a Safety.

The Safety bicycles with the steering-wheel in front were safer than the others owing to their greater length, and the fact that the rider was so far back, but they were not so fast, as less weight was on the driving-wheel. The rider could not be placed far enough back to put as much weight on the driving-wheel unless the pedal axle were divided. By adapting the swing frame with the divided pedal axle to such a class of machine, as much weight as desired could be placed upon the driver, and the advantages of the dwarf bicycles and of the Otto secured in one machine.

Concerning the Otto there seemed an anomaly—that they were better hill climbers when the wheels were as high as 56 in. than when smaller. As it was necessary for the centre of gravity to be over the points where the wheels touched the ground, there was a limit to the steepness of hill which could be surmounted.

He quite agreed with Mr. Boys as to the good qualities of the elastic spokes. He considered they were correct in principle.

Mr. Boys showed that even in the case of the steepest hills the amount by which the points of contact of the wheels with the ground were advanced was so small as to produce none of the effects supposed by Mr. Jones. In fact the hill-climbing power of the machine was perfectly well known.

Mr. Phillips felt sure that the slow pedalling was a far more important factor than the diminished wind resistance in the cause of the excellence of the Safeties. He had not intended to represent that the clutch gear was as good as the differential, but that at present the differential was greatly superior; he however believed that some device of the kind that he had spoken of—a perfect and instantaneous double-acting clutch—would be better than either.

He had not seen Mr. Burstow's clutch mentioned by Mr. Boys.

In speaking of the loss of power due to perpetually bending steel driving bands he did not refer to the very thin bands of the Otto, but to driving bands with holes to fit over pins some four or five times as thick.

The Chairman considered it an open question whether the path of a bicyclist were really wavy as theory seemed to show. He had often watched a bicyclist and it was almost impossible to believe that he did not travel in a straight path. He thought this question worthy of more attention. He had heard it asserted that no advantage could be gained by the use of artificial cycles over natural legs, but it must be remembered that legs were implements fitted for other purposes besides running, such as jumping and climbing. Again, no one supposed that a horse could carry on his back such a load as he could easily draw in a carriage on a road; here the extra weight of the carriage corresponded to the addition of the bicycle.

As in many other industries, bicycle and tricycle construction depended to a large extent for its success upon the perfection of many details of construction; as instances of important details he referred to rubber, steel wire, steel stampings, and driving-gear. Having made some remarks on the necessity of good roads he expressed the opinion that in time cycle ways might be laid down with advantage.

It was a mistake to suppose that cycling was only suitable for the young and active; people of all ages and conditions might enjoy the benefits of the wheel. The advantage of a sound machine to a labouring man, or of a hand-driven machine to a lame man, was inestimable, while invalids could even enjoy a run to the seaside in a Coventry-chair without the annoyance of cabs, railway stations, and trains. Having proposed a hearty vote of thanks to Mr. Phillips for his paper, he brought the proceedings to a close.

ALFRED TRIBE

ON November 26 died, after a very short illness, Mr. Alfred Tribe. He was born in London forty-six years ago in humble circumstances, and his first acquaintance with science seems to have been obtained as a boy at the Royal College of Chemistry. While waiting upon the students there he acquired whatever knowledge he could, and repeated in a back kitchen at home many of the experiments he had seen them perform. Prof. Hofmann, pleased with his desire for knowledge, gave him every encouragement and assistance in his power. At the age of sixteen he entered into the service of Dr. Medlock, then of Dr. Forbes Watson, and afterwards he assisted Prof. Williamson, of University College. He then went to Dr. Bernays, who after some time induced him to spend a year at Heidelberg under Prof. Bunsen, and kept his place at St. Thomas's Hospital open for him while he was away. On his return he continued to act as laboratory assistant and Demonstrator of Chemistry.

Twenty years ago he became my private assistant, and remained head of my laboratory till his death. During the same time he held the Lectureship on Metallurgy to the Medical School of the National Dental Hospital, and since 1874 he has been Lecturer on Chemistry and Director of Practical Chemistry in Dulwich College.

He became successively a Fellow of the Chemical Society, of the Institute of Chemistry, and of the Society of Chemical Industry.

Mr. Tribe was pre-eminently a scientific investigator. He loved patient and original research, and all his work was most carefully and honestly done. He published a large number of papers, some in his own name, and others in conjunction with myself. His first paper was on Sulphide of Ammonium, his second on the Expansion of Bismuth at the Freezing-point. His more important inquiries were connected with the occlusion of hydrogen by copper and the rarer metals, and especially a series of experiments on the distribution of the electricity in an electrolyte traversed by a current. The curious and suggestive results of this investigation appear in abstract in the *Proceedings* of the Royal Society for January and June, 1881, but they are most fully expounded, with coloured illustrations, in the second edition of Mr. J. E. H. Gordon's Treatise on Electricity and Magnetism."

His most important research in conjunction with myself is contained in a series of papers on the Copper-Zinc Couple, published principally in the *Journal* of the Chemical Society. He was the first to observe the greatly enhanced chemical power of zinc when covered with spongy copper. Whatever value there was in this extended research was due to his original suggestions, as much as to his careful manipulation. The same credit is due to him with regard to the series of papers on the aluminium-iodine reaction, the last of which was read only the night before he was taken ill. His discovery of these two new methods of acting upon chemical compounds was productive of many new substances, including the aluminium alcohols.

In addition to these chemical inquiries, we worked together on some electrical matters—describing an air-battery, that is, one in which the oxygen of the air took part; some experiments on thermal electrolysis; and, more particularly, the chemistry of the secondary batteries of Planté and Faure. The results of this investigation were first made known through the pages of NATURE, and were afterwards collected together in a separate treatise.

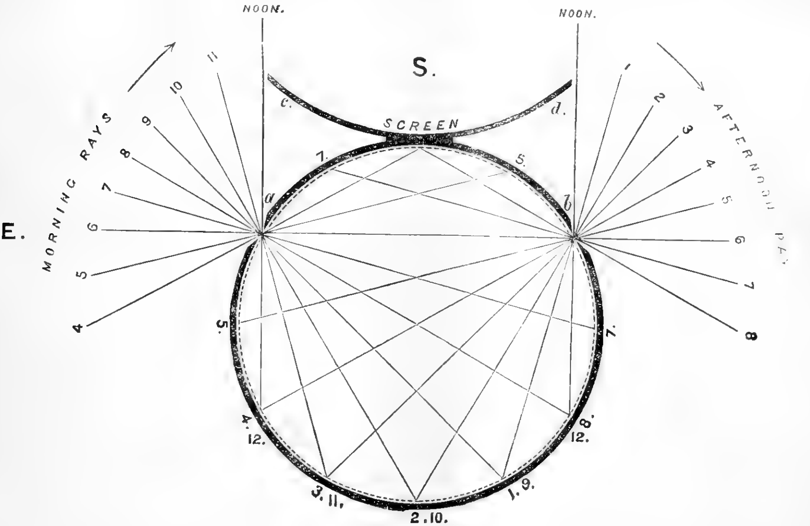
As a teacher of science, Mr. Tribe was very successful. He had the art of communicating his own enthusiasm to his laboratory students, and many of them have distinguished themselves since at the Universities or elsewhere. Only the week before his death he had the satisfaction of knowing that his favourite science was to receive a more worthy share of attention in the Dulwich College.

At these pursuits Mr. Tribe worked earnestly and continuously, being little known beyond his laboratories and his home. His widow, and four surviving children, together with a small circle of intimate friends, will however long remember the thorough uprightness of his character, and the self-denying purpose of his life.

J. H. GLADSTONE

JORDAN'S PHOTOGRAPHIC SUNSHINE RECORDER

UP to the present time the only instruments in general use for registering the duration of sunshine are modifications of the original apparatus invented by the late Mr. J. F. Campbell, of Islay, in 1853, the essential part of which consists of a clear glass globe capable of condensing the solar rays sufficiently to burn a trace on a card placed within its focal range. New forms of instruments have, however, been lately devised, and in the International Inventions Exhibition there were exhibited two Sunshine-recorders differing entirely from those hitherto used, the results being obtained by means of photography. Prof. McLeod's instrument was described in NATURE (vol. xxxi. p. 319), and we now give particulars of Mr. Jordan's photographic Sunshine-recorder. This instrument is of very simple construction. The working part consists of a cylindrical box or dark chamber $2\frac{1}{2}$ inches diameter and $3\frac{1}{2}$ inches long, mounted on a suitable stand having the means of adjustment to suit the latitude of the station where used. This cylinder is pierced with two small rectangular apertures or knife-edged slits, and, being placed in a position facing south, the rays of sunlight pass directly through these apertures and are received on the sensitised surface of a photographic paper or chart placed inside. By reason of the earth's rotation, the spot of sunlight thus obtained travels over the chart in a more or less curved line (according to the season), marking its path by a clearly-defined blue trace, which can be rendered permanent by simply immersing the paper for a few minutes in cold water. The position of the sun in relation to the instrument at the different hours of the day will be understood by reference to the figure, which is a cross-section through the cylinder; the dotted circle shows the position of the prepared chart, The screen, *c d*, is for the purpose of cutting off the rays from the eastern aperture at noon, and at the same time



allowing them to pass through the western aperture; it also forms a protection from rain and diffused light.

Observations made with this instrument prove that photography is well adapted for recording the duration of sunshine, and under some conditions it has advantages over the burning method. At those times when the atmosphere is perfectly clear the two methods give similar results, but when the sun is partially obscured by haze or thin cirrus cloud there is a difference in the records obtained. The result of a month's comparative observations, taken in June last, gave an excess of 11 per cent. of sunshine recorded by the photographic process, this variation being mainly due to a hazy atmosphere near the horizon about the times of sunrise and sunset.

METEOROLOGY IN THE NEW ENGLAND STATES[1]

THE New England Meteorological Society was founded in June, 1884, with a membership of 9, which at the close of its first year had risen to 95. Notwithstanding this very modest commencement, it has succeeded, largely through the generous co-operation of friends who have from time to time contributed liberally to its resources, in keeping its expenses within its income, while at the same time it has regularly published its *Monthly Bulletin* of eight pages, including a weather-map for the month; largely added to its observing stations; and largely extended the sphere of its operations. The annual fee for membership, which constitutes the whole income of the Society, is three dollars.

During its first year, ending last October, the Society has addressed itself more particularly to the securing of a corps of reliable observers of meteorological phenomena, with special attention to rainfall and temperature; the publication of the *Monthly Bulletin;* the dissemination of the daily indications of the U.S. Signal Service; the local display of weather-flags; and the special investigation of thunderstorms. The first number of the *Bulletin* contained reports from forty-five observers; but, so vigorously was this important branch of the Society worked out, that in September the number had risen to 123 observers. The greatest attention has been given to secure uniformity in the instruments and methods of observation. In the last-published *Bulletin* the amount of precipitation and the mean temperature are given in Table I. for thirty-five places, these being at the same time compared with the averages of previous years, which range from eleven to seventy-four years. Table II. gives a succinct summary of the results of the observations of temperature, pressure, humidity, and precipitation at the 123 stations, and the weather-map shows graphically the precipitation and range of temperature for the month.

A striking feature of the Society's work is its hearty co-operation with the U.S. Signal Service in the dissemination of daily forecasts of the weather, and the local display of weather-flags. A member of the Signal Corps has been assigned to this duty under the Society's control, with the gratifying result that local weather flags are daily displayed in upwards of 100 cities and towns of New England.

The special investigation of thunderstorms has been conducted under the supervision of the Secretary, Mr. Well

[1] *Bulletin* of the New England Meteorological Society, Nos. i. to xii. Nov. 1884, to Oct. 1885).

Davis, of Harvard College. The National Academy, which constitutes the trustees of the Bache fund, has granted 200 dollars for this work. Upwards of 400 observers are co-operating in the inquiry, and as regards one thunderstorm reports from 203 observers were received. The discussion of the important results already obtained will by and by appear in the *Bulletin*. A thorough investigation of thunderstorms, including the falls of rain, snow, and hail, with their successive propagation over the New England States, will be a highly important contribution to meteorology; and for the results of the investigation as it advances we shall look with much interest to the proceedings of this Society, which is among the very youngest but most active of the meteorological societies.

NOTES

We much regret to record the death of Sir Frederick J. O. Evans, R.N., K.C.B., F.R.S., late Hydrographer of the Admiralty, in his seventy-first year. Next week we hope to give a notice of Sir Frederick's career.

His Excellency the Minister of Agriculture, Industry, and Commerce in Italy, in order to favour and facilitate the application of remedies in solution, powder, or mixture against the cryptogams and parasites of cultivated plants, and especially the use of milk calx against Peronospora (mildew) of the vines, by a decree of November 9 will open an International Exhibition with prizes for pumps, watering and pulverisation implements. The Exhibition will take place at Conegliano in the Royal School of Vine-Culture and Œnology. The following prizes will be awarded:—1 gold medal and 500 lire; 3 silver medals with 150 lire each; 5 bronze medals. The Ministry of Agriculture will also purchase prize implements to the value of 1000 lire for distributing to the Agrarian Government depots, practical and special agriculture schools. Exhibitors must apply for admission to the "Direzione della R. Scuola di Viticoltura ed Enologia in Conegliano" not later than February 22, 1886. The demand must contain a short description of the instruments and the price of each object to be exhibited.

It is stated that the Mexican Government are about to establish a meteorological station among the highest mountains in Mexico, at an elevation of nearly 20,000 feet above the sea-level. Access to such a place must be always precarious, and frequently impossible for a long time together, hence it is necessary to make exceptional provision for rendering the instruments almost independent of human attention and supervision. The necessary apparatus is being constructed by Hottinger, of Zurich, and, as far as possible, all the instruments are being made to go for a year without stopping.

At the monthly meeting of the Council of the Sanitary Assurance Association arrangements were completed for the series of free lectures to be given by the Association at the Parkes Museum during January and February next. The first lecture is to be by Prof. Roger Smith, on "A Damp House," on Wednesday evening, January 20, and on the following Wednesday Mr. F. B. Jessett, F.R.C.S.Eng., will lecture on "Preventible Diseases."

The science certificates and prizes obtained by the students attending evening classes established by the Birmingham School-Board were distributed by Prof. Lapworth, LL.D., F.G.S., in the large hall of the Icknield Street School, on December 14. The report of the year's work, by the Board's demonstrator, Mr. W. J. Harrison, F.G.S., showed that some 5000 children are now receiving elementary instruction in science in the day-schools, while 500 teachers attend the evening classes. Prof. Lapworth afterwards delivered a very able and scholarly address. In consequence of the rapid growth of the system of science teaching, the Board has just resolved to enlarge the chemical laboratory at a cost of about 700*l*.

The Clothworkers' Company have promised to raise their annual subscription to the City and Guilds of London Institute from 3000*l*. to 4000*l*., provided the Corporation and Associated Livery Companies raise the total of their annual subscriptions to the Institute from 24,500*l*., the present amount, to 30,000*l*. This is probably the first step in response to Lord Selborne's recent appeal to the City Companies, on the double ground of public duty and self-interest, to add still further to their already munificent contributions to technical education. The capital expenditure on the building and equipment of the Central Institution, Exhibition Road, the Finsbury Technical College, and the South London School of Technical Art has been nearly 140,000*l*., but, as the late Lord Chancellor pointed out, the Companies cannot be said to have discharged their obligations to technical education, until the Institute wants no more pecuniary support and moral countenance. Until this distant goal is reached, said Lord Selborne, they remain in its debt, notwithstanding their already vast donations.

The statement, according to *Science*, that one of the chief applications of composite photography will be in the direction of producing more reliable portraits of representative men by combining the testimonials of individual artists, will probably be accepted by all who have followed the short but interesting career of this new invention. The suggestion that, by combining the individual conceptions of several artists, one would obtain a more reliable portrait than any of the components, was near at hand. The first such application was made by Mr. Galton himself. He made a composite of six medallion heads of Alexander the Great, and naturally claimed for the composite the combined authority of all the artists. In this way *Science* has recently come into possession of a new Shakespeare. In the case of Shakespeare the diversity amongst the several originals is strikingly evident, and thus a composite was needed to give a characteristic, individual, natural face. This suggested to Mr. W. C. Taylor the application of the same process to Washington's portraits. He has grouped the several portraits into three groups, owing to the differences of position of the portraits, and the accuracy of the work is well shown by the fact that the agreement amongst the resulting three composites is very close, while the originals show every shade of individual differences. These portraits were first published in the *Journal of the Franklin Institute*, and are given on a new and enlarged plate in the number of *Science* for December 11.

In pursuance of a resolution passed at the Medical Congress on Brain Diseases, held during the past summer at Antwerp, by which it was suggested that local conferences should be held to draw up trustworthy international tables of statistics on insanity, a Conference of Austro-Hungarian specialists will be held at Vienna on the 26th and 27th inst., with the object of revising and extending the nomenclature of mental disorders. Invitations to the Conference have been issued by four leading doctors of Vienna.

The work of spawning Salmonidæ at the establishment of the National Fish-Culture Association at Delaford Park has commenced, and it is expected that a large number of ova will be obtained. The establishment, which was opened in the early part of the present year, is now in excellent order, and all the fish that have been reared are doing well. It has been found necessary to increase the number of breeding-ponds in view of the extensive nature of the operations to be carried on next year.

The new aquarium for the Indian and Colonial fish at South Kensington is now in course of construction and will be on view at the next Exhibition. The tanks are to be erected at the back of the present aquarium, which will be maintained as heretofore, but as the fish to be exhibited require careful and special treatment no connection can exist between the two aquaria, which will be quite separate. It is to be hoped that the collection, when formed, will not be allowed to collapse at the termination of the forthcoming Exhibition, but that it will be maintained as a permanent institution, for an aquarium of foreign fish is much needed in London.

THE last issue of the *Izvestia* of the Russian Geographical Society contains a very interesting communication, by M. Yadrintseff, on the beginnings of settled life, being a contribution to the history of the rise of civilisation among the Ural Altayans. The paper is a *résumé* of an elaborate work on the subject which we hope soon to see published in the *Memoirs* of the West Siberian Geographical Society. M. Yadrintseff has had at his disposal very extensive materials, derived both from his own intimate acquaintance with the life of the native Siberians, and from a careful study of their history. Siberia is really one of the best fields for studying those intermediate phases of life which ultimately lead to the nomads becoming settled. Not only do the inhabitants of Siberia show us all possible stages in the transition from a nomadic life to that of settled agriculturists, but all these stages may also be studied under the varied aspects they assume when the modification goes on in different physical and geographical conditions, for example, in the forest regions, in the steppes, in the narrow valleys of the hilly tracts, and on the broad surfaces of the plains. It is easy to foresee what a valuable mass of information could be gathered in Siberia on this subject by an observer so well acquainted with his mother-country as M. Yadrintseff is; but it would be impossible to sum up in a few words the varied results to which the study has brought the author. The disappearance of entire civilisations like those of the Ural Altayans who immigrated into the plains of Siberia from the hilly tracts of the Altay, only add to the already great interest of the subject. We notice, moreover, the importance justly attached by the author to those intermediate phases which the nomad goes through when he abandons his former mode of life, and, by narrowing the region of his migrations, by staying at a permanent wintering place, and by merely migrating from a permanent summer dwelling to a winter dwelling, finally becomes a settled agriculturist; the relative facility with which this modification is undergone by the inhabitant of a forest region as compared with the difficulties met with by an inhabitant of the steppes; the similarity between many Siberian indigenes now passing through these intermediate phases of civilisation and the Germans at the time of Tacitus; and very many minor conclusions, all possessing great interest.

AMERICAN papers state that an aërolite or meteoric stone, which caused a loud detonation, heard throughout the greater part of Washington and Alleghany counties, Pa., on Saturday, the 3rd inst., fell upon the farm of Mr. Buckland, in Jefferson township, Washington county, near the West Virginia line. A mail carrier states that looking up he saw, moving high above him, a huge mass, which he described as resembling a great coal of fire as large as the largest barn he ever saw. There appeared to be attached to it an immense flame of a deep red colour, which tapered off into a darker tail. Instantly the noise which accompanied it ceased; the fire-like appearance, the flame, and the tail disappeared, and in their stead the stone assumed a whitish hue, which it retained until it passed out of sight. When the stone fell it broke into three pieces, but did not penetrate the earth to any great depth, as two-thirds of it remained above ground. It is grayish in colour, with a succession of red streaks, is irregular in form, and at least fifty feet in diameter.

A CORRESPONDENT of the *Times*, referring to Sir John Lubbock's discovery of much greater longevity of ants than has hitherto been believed, thinks that the same may be true with regard to the butterfly, although the common notion is that the butterfly's life is a short and merry one. The correspondent, who writes from Bournemouth, then relates the following incident:—"On August 15 last a fine peacock butterfly flew into our house through the garden door, and was caught and put under a large bell glass. On the following day another came in, and was also put under the glass. They were supplied daily with fresh flowers and a few drops of new honey, which they evidently much enjoyed. No. 1 died during a suddenly cold night, No. 2 lived until yesterday, December 14. Whenever the sun shone upon their cage, which was placed on a table near a large window of plate glass, they opened their beautiful wings and flew about vigorously, occasionally resting on a flower to thrust their trunks deeply into its corolla, or standing over and sucking up the drops of honey. The extraordinarily sensitive nervous system of these little beauties was indicated by the most rapid vibratile trembling of the wings directly the sunlight or the scent of fresh flowers reached them. When the sun was not out they usually remained perfectly still, with their wings closed, especially selecting to hang on the under side of a leaf. They showed great intelligence in distinguishing the freshly-gathered flowers and in deciding that honey was the right thing to eat, and I have seen one of them scramble with considerable difficulty across his cage through a tangle of leaves and stalks, determined to get to a particular leaf on which he wished to hang. After some unsuccessful attempts to reach it, he hooked it down with one foot, then held it with another, until he could get the rest of his legs upon it, having done which he appeared satisfied, shut up his wings, and hung himself upon it, topsy-turvy, to rest. If he failed to do what he wished with one leg, he immediately tried another, appearing to think that, having six at his disposal, it was foolish to waste much time on any one. But he only used his most anterior pair on very special occasions. How long each butterfly had lived before it was caught I do not know, but No. 2 lived in its glass cage 121 days."

THE amount of carbonic acid in the air has recently been measured by MM. Spring and Roland in a series of 266 determinations in the course of one year, the place being at Liége, in Belgium, having on one side a busy centre of the iron industry and on the other an agricultural district. The average obtained was 5·1258 parts by weight and 3·3526 parts by volume in 10,000 parts of air. This is considerably more than the air of Paris contains (4·83 and 3·168 respectively). Besides the plentiful carbonic acid from those iron-works, there is a large emission of the gas from the ground, which is rich in coal; indeed, cases of local heating often occur, with withering of the plants. To the relative abundance of carbonic acid the authors attribute the greater heat of Liége as compared with the surrounding regions, as the gas strongly absorbs heat-rays and limits radiation by night. A return of cold in May is thought to be due to the unfolding leaves diminishing the amount of CO_2, so that the nightly radiation is increased. The amount of CO_2 is considerably increased by a fall of snow (to 3·761 ten-thousandth parts by volume), except when the earth is already covered with snow. Cloud also gave an increase (3·571). The winter months gave a greater amount than the summer. The difference between day and night was but slight, nor had temperature nor rainfall a decided effect; but the rain in thunder-storms increased the amount. As to wind there were three maxima—viz. with north, north-west, and south-south-west winds, corresponding, apparently, to the directions of industrial centres. The CO_2 diminished in high winds and increased with a high barometer. These researches are the subject of a recent memoir to the Belgian Academy.

THE average heat-value of well-purified coal-gas at constant volume has been recently determined by M. Witz (*Ann. de Chim. et de Phys.*) as about 5200 calories per cubic metre at 0° and 760 mm. when the water formed is fully condensed. This value, got from a great variety of experiments with gas from different works, appears to make the generally-accepted figure of 6000 calories about 15 per cent. too high, and the calculation of gas motors is here concerned. The heat-value of the gas from one and the same works varied in the course of a year from 4719 to 5425 calories, which was more than the variation between different works. The influence of temperature and external pressure was not perceptible. The operations for purifying gas diminish the heat-effect, sometimes as much as 5 per cent. The gas of the last hour of distillation is (contrary to the usual view) less rich than that of the first hour. Dilution with oxygen lessens the heat-value; but in dilution with air, curiously, no such effect was observed; the heat of combustion was the same with six or with ten volumes of air.

IN his investigations of the changes of level of inland lakes (known as *seiches*), Prof. Forel has arrived at the simple formula $t = l / \sqrt{gh}$ for those movements, in which t expresses the time, in seconds, of a half oscillation of a uninodal *seiche*, l, the length, and h, the mean depth of the cross-section of the lake in which the variation is observed. This formula holds good for the lakes of Neuchatel, Brienz, Thun, Wallenstadt, and Geneva. An interesting confirmation of it is found by M. Forel in observations made by Mr. Russel with a limnograph on Lake George in New South Wales. This instrument had recorded 33 very regular *seiches* on the lake this year, and the duration of a whole oscillation proved to be 131 minutes. Now the length of the lake being 28,962 metres, the above formula gives, for the mean depth, 5·536 metres, or 18·1 feet. Mr. Russel states that the mean depth is between 15 and 20 feet.

THE prevailing direction of the winds on the shores of the Black Sea and the Sea of Azov has been recently studied in great detail, and in connection with the recent progress of meteorology with regard to wind generally, by M. Spindler, who has published his work, with maps, in the Russian *Maritime Review* (*Marskay Sbornik*). Four maps show the prevailing direction of the wind at 7 a.m. and at 1 p.m. during the four seasons of the year. During the winter a notable difference between the prevailing direction at these two hours of the day is seen only on the eastern shore; while in the spring and summer nearly everywhere on the Russian coast of the Black Sea these two directions differ by 90°, and at some places they are quite opposite to one another, thus showing that the predominating influence of the currents of air depend upon the different heating of land and sea.

IT is reported from Kara-hissar, in Asia Minor, that an earthquake shook that neighbourhood on Tuesday, December 2. In the hamlet of Kemin the earth opened for a length of about 40 feet, and from 3 to 5 feet wide.

THE last earthquake shock in Algeria was felt at Blidah on December 13, at 5 a.m. Subterranean noises were heard. The first shock, in Hussein Dey, near Algiers, was felt on December 3. at 8h. 23m. a.m. This has been proved by the stopping of a clock in a distillery.

HOW great are still the numbers of Carnivora in Finland may be seen from the following figures, given in the last issue of the "Statistical Yearbook" for Finland. In 1882 not less than 85 bears, 128 wolves, 407 lynxes, 4005 foxes, 76 gluttons, 240 river otters, 148 martens, 1583 ermines, and 3947 carnivorous birds were killed, for which an aggregate of 1646*l*. was paid in premiums by the Government. The ravages occasioned by Carnivora the same year were immense: they are estimated at 274 horses, 846 horned cattle, 5246 sheep, 168 pigs, 119 goats, 1681 reindeer, and 2366 domestic fowls. The greatest number of bears were killed in Viborg and Uleåborg (respectively 33 and 30), while most wolves were killed in the more densely-peopled Government of Tavastehuus.

AT the meeting of the Royal Physical Society of Edinburgh, held December 16, the following office-bearers were elected, viz.—President: Prof. William Turner, F.R.SS.L. and E., Edinburgh University; Vice-Presidents: John A. Harvie-Brown, F.R.S.E., Rev. John Duns, D.D., Prof. J. Cossar Ewart, F.R.S.E.; Secretary: Robert Gray, V.P.R.S.E.; Assistant-Secretary: John Gibson; Treasurer: Charles Prentice, F.R.S.E.; Librarian: William Evans Hoyle, F.R.S.E.; Council: John Hunter, F.C.S., Robert Kidston, F.G.S., A. B. Herbert, Prof. James Geikie, F.R.S., G. Sims Woodhead, F.R.C.P.Ed., Hugh Miller, F.G.S., Arthur W. Hare, M.B., R. Milne-Murray, M.R.C.P.E., H. Moubray Cadell, B.Sc., R. H. Traquair, F.R.S., R. Sydney Marsden, D.Sc., F.R.S.E., Benjamin N. Peach, F.G.S., F.R.S.E.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by the Rev. Spencer Fellows; a Black-backed Jackal (*Canis mesomelas*) from South Africa, presented by Mr. J. Robson; a Slender-billed Cockatoo (*Licmetis tenuirostris*) from Australia, presented by Mrs. Sturt Cavell; a Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. T. E. Gunn; three Wild Ducks (*Anas boschas*), British, presented by Mr. C. T. McNiven; a Lapwing (*Vanellus vulgaris*), British, purchased.

OUR ASTRONOMICAL COLUMN

TOTAL SOLAR ECLIPSE, 1886 AUGUST 28–29.—The eclipse will be total throughout the Island of Grenada. The *Greenwich* mean times of beginning and ending of totality for any point in the island may be found from the formulæ:—

$$\cos w = -4{\cdot}99267 - [1{\cdot}77822] \sin l + [1{\cdot}26284] \cos l \cos (\lambda + 48^\circ\ 13'{\cdot}5$$
$$t = 1\text{h. } 12\text{m. } 41{\cdot}7\text{s.} \mp [2{\cdot}04698] \sin w - [3{\cdot}24330] \sin l$$
$$- [3{\cdot}84970] \cos l \cos (\lambda + 82^\circ\ 53'{\cdot}0),$$

where l is the *geocentric* latitude of the place, λ its longitude from Greenwich, taken *negatively*, and the quantities in square brackets are logarithms; upper sign for beginning, lower for ending.

For long. 4h. 6m. 20s. W., lat. 11° 59'·5 N. near the *southern* extremity of the island, totality begins at 19h. 11m. 0s. local mean time, and continues 3m. 42s. ☉'s altitude 20°.

In long. 4h. 6m. 40s. W., lat. 12° 15'·0 N. near the *northern* extremity of the island, totality begins at 19h. 10m. 37s. local mean time, and continues 3m. 37s.

At Carriacou I. (Grenadines)—

Totality commences at 19h. 11m. 45s. local M.T.
Duration ... ... 3m. 21s.
Sun's altitude ... ... 20°

FABRY'S COMET.—Dr. H. Oppenheim continues his ephemeris of this comet in the *Dun Echt Circular*, No. 102, as follows:—

Ephemeris for Berlin Midnight

1885	App. R.A. h. m. s.	App. Decl. ° '	Log. Δ	Brightness
Dec. 28 ...	23 48 29 ...	+20 52·6 ...	0·0849 ...	1·6
29 ...	47 14 ...	54·8		
30 ...	46 2 ...	57·3		
31 ...	44 52 ...	21 0·0		
32 ...	43 45 ...	3·0 ...	0·0850 ...	1·8

β CYGNI OR 6 CYGNI?—M. Flammarion in the December number of *L'Astronomie* falls into a curious confusion with regard to these stars. Dr. Ball had found the parallax of B.A.C. 6579 (B) to be $+0''{\cdot}482 \pm 0''{\cdot}054$, and following Bode's numbers called the star 6(B) Cygni. Unfortunately, however, M. Flammarion supposed Dr. Ball referred to Flamsteed's 6 Cygni, which is β Cygni, and based an article on the supposed determination of its parallax. The mistake was a very easy one to make, but at least the Dunsink observations are not to blame, for Dr. Ball gives not only the place of the star he observed but its number in three catalogues—Groombridge, Struve's *Mensuræ*, and the *Durchmusterung.*

BARNARD'S COMET.—Dr. H. Oppenheim (*Astr. Nachr.*, No. 2697) has computed the following elements and ephemeris for this comet:—

Perihelion Passage = 1886 May 14·1430 Berlin M.T.

$$\left.\begin{aligned} \omega &= 116^\circ\ 31'\ 57'' \\ \Omega &= 66\ 22\ 12 \\ i &= 94\ 8\ 7 \end{aligned}\right\}\text{Mean Eq. } 1885{\cdot}0$$

$$\log. q = 9{\cdot}74184$$

Error of the middle observation:—

$$\delta\lambda = +4'' \qquad \delta\beta = -3''.$$

The elements resemble those of Comet 1785 II.

Ephemeris for Berlin Midnight

1885	App. R.A. h. m. s.	App. Decl. ° ′	Log. Δ	Brightness

32 ...	11 1	... +8 14·6	... 0·2359	... 1·5

The brightness on December 5 is taken as unity.

THE PULKOWA OBSERVATORY.—From his Report, presented May 25, 1885, it appears that M. O. Struve was chiefly occupied, during the year to which the Report refers, with work connected with the erection of the great 30-inch refractor. Various unexpected delays had occurred, in connection chiefly with the construction of the dome, but, at the time of writing his Report, M. Struve states that regular observations could be commenced immediately. He expresses himself as greatly pleased with the mounting of the instrument, which has been designed and constructed by the Repsolds. At present the dome is moved by hand, but it is hoped that this may eventually be done by electricity, and that motive power will thus be obtained sufficient to overcome the hindrance to the rotation of the dome caused by snow and frost. It is proposed to use the great refractor for observing such double-stars as are beyond the reach of the 15-inch equatorial, and to undertake observations of interesting nebulæ, as well as spectroscopic researches in cases where the great optical power of the instrument will be of special importance. We learn from *Science* that M. Struve has written to Messrs. Alvan Clark and Sons, acknowledging the excellent performance of the object-glass furnished by them, and announcing that the Emperor of Russia had conferred on them the Honorary Gold Medal of the Empire.

Notwithstanding the additional cares and labours thus imposed on the staff of the Pulkowa Observatory, further increased by M. O. Struve's regrettable illness, the usual work in the various departments has been kept up with vigour, and it is evident that the famous Russian institution, under its present superintendent, will continue to maintain its great reputation.

SUSPECTED "NEW" STAR.—It is announced in the *Dun Echt Circular*, No. 104, that Mr. Gore, observing with a binocular on the evening of December 13, found a reddish star of 6th mag., and about 20′ following χ' Orionis. This object is not given by Harding, Lalande, Heis, Birmingham, or the Bonn maps. On December 16 Copeland and Becker, observing at Dun Echt, found it of the 6½ mag., and of an orange-red colour. It has a very beautiful banded spectrum of the third type, seven dark bands being readily distinguished with the prism. The bright intervals seem full of bright lines, especially in the green and blue. The mean place for 1885 is R.A. 5h. 48m. 59s.; Decl. + 20° 9′·4.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1885 *DECEMBER* 27—1886 *JANUARY* 2

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 27

Sun rises, 8h. 8m.; souths, 12h. 1m. 27·7s.; sets, 15h. 55m.; decl. on meridian, 23° 19′ S.: Sidereal Time at Sunset, 22h. 20m.

Moon (at Last Quarter on Dec. 28) rises, 22h. 18m.*; souths, 4h. 56m.; sets, 11h. 23m.; decl. on meridian, 4° 19′ N.

M signifies maximum; *m* minimum.

Meteor Showers

The principal periodic shower at this time is that of the *Quadrantids*, R.A. 225°–232°, Decl. 55°–60° N., seen on January 2 and 3. As the radiant-point rises after midnight, the shower must be looked for during the morning hours. A shower with radiant near Aldebaran may be looked for during this week and throughout January.

Stars with Remarkable Spectra

Mira Ceti, R.A. 2h. 13m. 36s., Decl. 3° 29′·6 S., should be examined with the spectroscope on every favourable opportunity now that it is approaching its maximum. It is a fine example of Secchi's third type.

GEOGRAPHICAL NOTES

Two papers in the December number of the *Proceedings* of the Royal Geographical Society are of unusual interest. The first is Mr. F. Simons's account of his exploration of the Goajira peninsula of the United States of Colombia; the second, a series of letters, hitherto unpublished in English, from Colonel Prjevalsky, translated by Mr. Delmar Morgan. Mr.

Simons first describes the topography of the little-visited peninsula in some detail, and then gives an account of the tribe of Indians inhabiting it, which is of exceeding interest, so remarkable are many of their customs. Their system of compensation—consisting of tear and blood-money, or fines for tears or blood supposed to be shed—is one of the most extraordinary ever found amongst a primitive people, extending not only to injuries, wilful or accidental, done to one man by another, but to accidents happening to a man himself. Every man is a hostage for every one of his clan, and is liable to be called upon to pay various fines for the acts of another; if a man borrows an animal of another and is thrown off, the lender has to pay, first, the relatives of the mother, then the relatives of the father, and, lastly, the friends of the borrower. If a man injures himself he is forced to pay his mother's relations for his own blood which has been spilt, his father's for the tears which they are presumed to have shed, and his friends for the sorrow the accident has caused them,—and all this if he has only cut his finger with his knife. Many other curious customs are also recorded. Colonel Prjevalsky's letters describe certain districts around Lob-Nor, and the route to Cherchen and Kiria. The work of the Admiralty Surveys for 1884 is detailed from the Hydrographer's report. Sir Frederic Goldsmid writes on the geographical nomenclature of places between Merv and Herat, and Admiral Irminger, of the Danish Navy, explains, in a letter to the secretary, the so-called subsidence of one of the Faroe Islands, which turns out not to have been a "subsidence" at all.

M. POTANIN has again written to the Geographical Society, from Si-nin, under date of April 29. The expedition was continuing its work without the least hindrance, MM. Potanin, Stassy, and Berezovsky exploring the region in all directions, after having wintered in three different towns; the astronomical determinations were also made, and the population, far from hindering the surveys, assisted them. A Tangut, in the service of M. Potanin, is a valuable aid in making collections of insects. MM. Potanin and Skassi left San-chuan on April 15, taking a northerly direction to reach the Si-nin River (called Nimbimuren in its lower course). Its valley is inclosed between high walls of loess, and at three different points it is narrowed by crags of gneiss, where some gold is dug. In the Lau-va-sya gorge the limestone crags are covered with numerous and beautiful *marmites de géant*, one of which has a diameter of 160 centimetres. Above this gorge the valley reaches a width of more than two miles, and two towns, Lau-va-sya and Nimbi, are situated there. They are peopled with Mongols, many of whom are Mussulmans; the villages are peopled with Chinese. Si-nin was reached on April 24, and M. Potanin proposed to leave it soon for Min-cheu, *via* Gui-Dui, so as to connect his surveys with those of M. Prjevalsky.

THE German Emperor has ordained that the harbour discovered on the north-east coast of Kaiser Wilhelm's Land, north-west of Port Constantine, shall henceforth be known as "Friedrich Wilhelm's Hafen," and the bay near it "Prince Heinrich's Hafen"; the large navigable river discovered east of Cape de la Torre as the "Kaiserin Augusta Fluss," while Beaupré, situated in the middle of the peninsula will now be called "Varzin." "Neu Mecklenburg" will be substituted for New Ireland, "Neu Lauenburg" for the Duke of York group, and "Neu Pommern" for New Britain, the largest island of the Bismarck Archipelago.

THE voyage of the *Vega* along the north coast of Europe and Asia seems likely to bring about another result, namely, the connection of the Petchora with the Obi by a route presenting fewer dangers than the navigation of the Kara Sea. Thanks to the continuous efforts of MM. Sidoroff and Sibiryakoff, the exploration of the Northern Urals, with a view to discover the best routes for connecting the great river of North-East Russia with the chief artery of Siberia, is being busily prosecuted. It appears now, from a communication by M. Nosiloff to the Russian Geographical Society (*Izvestia*, iv. 1885), that there are in the Northern Urals passes which would permit of establishing an easy link between the two basins. The best of them seems to be the Schokuriinsk Pass, the same that Prince Kurbsky availed himself of in 1449 to reach the Obi. A portage, only 98 miles long, leads from Kuya—a village on the Petchora, within easy reach of steamboats—to the Sygva River, a tributary of the Sosva, which appears to be navigable for boats up to a point distant only 35 miles from the pass over the Ural Mountains. The Sygva has a depth of from 4 to 7 feet, and a width of 150 to 350 yards; while the Sosva, 6 to 18 feet deep, forms an excellent channel for even larger vessels. As to the portage itself, its highest point reaches only 1450 feet above the sea, and 1150 feet above the Sygva; and a railway less than 100 miles long would avoid all those difficulties which are now presented by the navigation of the Kara Sea and the ice-bound Gulf of Obi. Another pass, Voikarsky, is at almost the same distance, and its highest point rises about 1650 feet above the sea. The existence of these deeply-indented valleys, and the general configuration of the region, together with the direction of the rivers, once more raises the question, whether the Northern Urals, instead of being *one* winding mountain-chain, are not rather a complex of several smaller chains having a north-easterly direction, and arranged in *échelons* from south to north. It would be most desirable to have a thorough orographical and geological exploration undertaken in connection with the above work, in order to settle one of the most important questions as to the orography of the northern part of the great Russian plain.

WE notice in the last issue of the *Izvestia* of the Russian Geographical Society (1885, iv.) the following information communicated by Gen. Meyer with regard to the Transcaspian region. The great ranges of mountains which bear the names of Great and Little Balkhans, Kuren-dagh, and Kopet-dagh, and are continued on the Persian frontier under the names of Aselma, Deireghez, Kelat, and so on, diminish in height towards the east, until they almost entirely disappear about Sarakhs. The chief range reaches, however, 6000 to 7000 feet, with separate peaks 8000 feet high, and the upper parts of its northern slope are covered with snow nearly all the year round. Notwithstanding this, the streams which flow from these mountains into the steppes are remarkably poor; the slates, of which the slopes of the mountains consist, giving the water a free passage into the soil. The ancient inhabitants knew how to utilise this structure of the soil by making their *kerizes*, or wells, connected together by underground galleries, which, after being dug thus for a mile or two, yielded water for irrigation. These wells are now unfortunately mostly in a bad state, and few of them are of any use. The much-talked-of dams on the Murghab and Heri-rud would not be of great use, as the high water in both rivers comes in the spring, and not in the summer when the fields are most in need of irrigation. The characteristics of the ground are strikingly uniform, a terrace with a soil of dry clay, intersected by small ravines, in all cases spreading at the foot of the mountains. The climate is very dry, but fevers are common, probably in consequence of the very rapid variations of temperature from a hot day to a cold night. At Askabad the yearly average temperature is 24°·8 C., the extremes being 31°·5 and − 8°·1. Up to a height of 4000 feet the mountains are covered with a steppe flora. Higher up they are mostly quite devoid of vegetation. The *artcha*, reaching sometimes twenty-five feet, but never growing in forests, is excellent as fuel, but cannot be employed for building. A few willows, poplars, and rushes are sometimes met with along the streams. In the spring the plains are all covered with herbaceous vegetation, which is, however, unfit for pasture. Grazing-grounds are met with only on sandy ground about Akhal. Further east, towards Merv, there are no pasture-grounds, but trees are more numerous. When watered the soil gives good crops: wheat, barley, the Khiva millet, lucerne; cotton and silkworm trees grow well on watered fields, as also poplars, willows, plane-trees, and various kinds of brushwood.

THE following information as to the population of the Transcaspian region, communicated to the last issue of the *Russische Revue* (1885, iv.), by M. Seidlitz, may complete the above. The aggregate population of the region is estimated at from 214,000 to 260,000 inhabitants, including Merv—that is, much below previous estimates. The whole region being divided into the districts of Akhal-tekke, Krasnovodsk, Manghishlak, Merv, and Tejen, it appears that the population of the three former districts numbers about 93,000, who live on agriculture in Akhal-tekke and on cattle-breeding in Krasnovodsk and Manghishlak. The agriculture of Akhal-tekke is considerable, the crops of 1883 having yielded no less than 190,000 quarters of wheat, barley, and *Sorghum cernuum*. The cattle in the three districts are estimated at no less than 44,000 horses, 76,000 camels, and more than 600,000 sheep, to which nearly 130,000 horses, 193,000 camels, and one million and a half of sheep must be added for Merv and Tejen. The culture of cotton and of the silkworm in Akhal-tekke is also worthy of notice. The population of Akhal-tekke consists of Tekke-Turcomans (8400 *kibitkas*, about 42,000 souls), with some 1160 Persians and Tartars, 930 Armenians, and 340 Russians, without families. Askabad, the chief town of this district, has already an important trade. The inhabitants of the Krasnovodsk and Manghishlak districts, on the contrary, are nearly all nomads, and their chief towns, Krasnovodsk and Alexandrovsk, are miserable hamlets with less than 400 inhabitants each. The oasis of Merv, with its 32,000 *kibitkas*, is well peopled. The *bazaars* of the chief town are very animated, 8000 to 10,000 people gathering there twice a week. Since 1785, when the Sultan-bend dam on the Murghab was destroyed by the Ameer Murad Khan, the area of the oasis has much diminished, and it occupies now only a length of 160 miles, and a width of some 13 miles. The town Bairam-kalæ was abandoned for want of water. The Tekke Turcomans, who have inhabited the oasis since 1857, when they drove away the Saryks, are divided into two stems, the Okhtamyshs and the Tokhtamyshs. The richer of them live in felt tents, while the poorer ones make huts of clay of the same shape as the felt tents. These settlements and villages are not permanent, and may be changed at the first signal of alarm. In fact the population is too numerous for the watered area. As to the fertile oasis of Tejen, on the Heri-rud, it was formerly visited only in the summer. It has now some 7500 Tekke inhabitants, who have immigrated from Merv, Akhal, and Atek.

MR. SHIPLEY, the American Consul at Auckland, New Zealand, reports to the State Department at Washington, the following facts about a new volcano in the Pacific Ocean :—"At daylight on October 13 we observed dense volumes of steam and smoke clouds ascending. We sailed sufficiently near to see that it was a submarine volcanic eruption. Considering that it was not prudent to approach any nearer that night, we lay to until morning. We then approached to about a distance of two miles. I have not words to express my wonder and surprise at its changing splendour. Eruptions take place every one or two minutes, changing in appearance every second, like a dissolving view. I can only say that it was one of the most awfully grand sights I ever witnessed on the high seas. As near as I was able to calculate the position of the volcano, it is about fourteen miles from the island of Honga Tonga. As to the size of the island thrown up, I am unable to state it correctly, there being so much steam and cloud hanging over it; but I judge it to be at least two or three miles long, and 60 feet high, in lat. 20° 21′ S., long. 175° 28′ W."

THE PARIS ACADEMY OF SCIENCES

THE yearly meeting of the Paris Academy of Sciences took place in the large hall of the Institut on December 2. Rear-Admiral Julien de la Gravière was in the chair. He read a short paper summarising the *éloges* of eight members who died during the past twelve months. This number is unusually large in a body of sixty-six.

M. Bertrand delivered two addresses on M. Lagourneria, a geometer, and M. Combes, an engineer, who died some years ago, after having enjoyed the academical honours during many years.

The number of prizes delivered by the Academy is increasing yearly, not less than thirty-three being offered for competition in 1886. The total of the sums to be awarded is more than 3000*l.*, exclusive of some of which the value is to be determined according to the merits of competitors, and the Bréant Prize for a cure for cholera. Dr. Ferran was not even mentioned in the verdict, and the interest of the 4000*l.* was given to several writers on the etiology of cholera.

Some of the prizes for 1885 were not awarded, for want of competition, although, except a very few, they are open to every nation, and memoirs can be written in any language as well as in French. A large number of prizes were not delivered for want of merit in the contributions sent. Some of them were awarded to scientific writers who have published volumes on topics connected with the subject-matters. Of this last class we may mention, *inter alia*, "Memoire sur la Marche et l'Extension du Choléra Asiatique des Indes Orientales," &c., by Dr. Mahé, representing France at Constantinople; "Contributions à l'Etude de la Fièvre Typhoïde," by Dr. Pietro Santo; "Statistique de l'Industrie minérale et des Appareils à Vapeur en France et en Algérie," by M. Keller; "Contributions à l'Etude statistique du Suicide en France," by Dr. Jules Socquet; "Histoire de l'ancienne Académie de Marine de Brest," by M. Donneaud du Plan, Librarian of the Navy at Dieppe.

Amongst the most important prizes awarded we notice the following :—

M. Amsler Laffon, of Shaffhouse, for his instrument for polar planimetry, as presented by Mr. Scott Russell to the Institution of Naval Architects in 1880 (Monthyon Medallist for Mechanical Arts).

M. Colladon, of Geneva, for the application of compressed air as a motive power in tunnelling Mont Cenis (Fourneyron Medallist).

M. Thollon, for mapping the solar spectrum in the Bischoffsheim Observatory, Nice (Lalande).

Dr. Spörer, of the Potsdam Astro-Physical Observatory, for his studies on solar spots (Voltz).

Dr. Edlund, member of the Academy of Sciences of Stockholm, for his memoir on the origin of electrical tension of the atmosphere. He considers this tension to be produced by the rotation of the earth, which is a magnet. The soil being made negative, the atmosphere becomes positive by induction. The difference of tension resulting from his calculations is 223 volts per kilometre altitude. No less than twelve memoirs were sent —five in French, four in German, and three in English (Boydron Prize). The memoir of Dr. Edlund had been already printed and published.

M. Gernez, for his discoveries in rapid solidification of supersaturated liquids.

M. Halphen, a major in the French Artillery, took the Petit d'Ormay Prize for the *ensemble* of his mathematical work and principally the solution of the following problem :—Trouver les équations différentielles qui se reproduisent par une substitution linéaire.

The Monthyon Prize for discoveries in connection with unhealthy arts has been given to M. Chamberland, chief assistant of M. Pasteur, who invented a filter in chinaware which stops even microbes.

The Government Prize was given to M. Joannes Chatin for his study of the sensation organs of invertebrate animals.

The Cuvier Medallist for this year is Prof. Van Beneden, of the Louvain University, for half a century of work in physiology.

THE NEW ZEALAND INSTITUTE

THE volume of *Transactions* of the New Zealand Institute for 1884 was issued to the members in May of the present year. It is edited by Dr. Hector, and contains fifty-five memoirs, which, read before the various affiliated societies, have been deemed worthy, by the Governors of the Institute, of publication. While the papers on biological subjects occupy three-fourths of the space devoted to the transactions, those on geology are but few in number. Among the more important of the zoological memoirs may be mentioned the following :—"Descriptions of New Zealand Micro-Lepidoptera," by E. Meyrick (pp. 68–149). In continuation of his previous memoirs we have here full details and an analysis of the following families :— Scopariadæ; while no species of this family is common to New Zealand and Australia, the author has included in his memoir descriptions of the known Australian species of the genera Scoparia, Tetraprosopus and Xeroscopa. Fifty-eight species of the first and sixteen species of the last genus are described. Pyralidæ: Hydrocampidæ; these families are each represented by a single species, neither of which is, in a strict sense, indigenous, *Asopia farinalis* being introduced from Europe. The representative of the latter family, *Hygraula nitens* (Butl.), being regarded as a recent migrant from south-east Australia. Pterophoridæ; eleven species are described: one is closely allied to a European form, one is Australian; the other nine are all endemic. In a supplement a number of additions to the previously-published list of species of Crambidæ and Tortricidæ are described. "Further Notes on Coccidæ," by W. M. Maskell. The author comments on our notice this time last year of the roughness of the plates in Vol. XVI. While we agree with him that all biologists are not artists, yet we venture to think that it is not too much to expect that there should be one artist at Wellington who could execute plates in a style worthy not only of the New Zealand Institute, but in keeping with the excellent typography of the volume. Thus, the very "lettering" of the plates in the present volume is not only bad, but misleading, Vol. XIV. being misprinted for Vol. XVII., and Plate

8 for Plate 7. We notice, however, an improvement in the lithography. In his notes Mr. Maskell describes several new species, and advances our knowledge of the New Zealand fauna very considerably. In a paper on the spiders of New Zealand, Mr. A. T. Urquhart describes and figures a great many new species, chiefly from the neighbourhood of Auckland. Prof. Jeffrey Parker gives notes on the skeleton and baleen of a Fin Whale (*Balænoptera musculus*), and Mr. S. Mieson gives some interesting details about a plague of rats in Nelson.

Among the botanical memoirs may be noted those of Mr. T. Kirk, on the flora of Stewart Island. Prefaced by a short sketch of the island, and the facts previously known as to its natural history, Mr. Kirk gives the results of his investigations of its flora made during two visits in January, 1882, and in January, 1884. So far as at present known the flora of the island comprises about 380 species of Phænogams, and nearly 70 species of Pteridophytes. The area of the island is estimated at 640 square miles. Attention was at once attracted by the blaze of crimson presented by the flowers of *Metrosideros lucida*, often flecked by the beautiful pale racemes of *Weinmannia racemosa*. *Veronica salicifolia* occurred by the side of water-courses, but was far from common. The soil was often carpeted with a compact growth of the charming liliaceous plant *Callixene parviflora*, with its elegant drooping flowers. The terrestrial orchids formed a marked feature in some parts of the forest. *Coryanthes oblonga* and *C. rivularis* produced their attractive flowers literally by thousands. Arborescent ferns were abundant, the most abundant being *Dicksonia squarrosa* and *Hemitelea smithii*. The crest of Mount Anglem, the highest peak of the island, was ascended. The weather, unfortunately, was unfavourable, the driving snow obscuring the prospect. A splendid Alpine flora was discovered. *Dracophyllum muscoides* formed a compact dark green sward gemmed with white flowers; several species of Coprosma, *Ranunculus lyalii*, the beautiful *Ourisia sessiliflora*, also *O. cæspitosa*.

On exposed portions of the coast on both sides of the island *Olearia angustifolia* was found; it is one of the grandest of flowering plants. Varying in size from shrubs of about 6 feet high, to a tree of 20 feet, the snowy ray florets, with the dark purple of those of the disk of the innumerable flower heads, set off by the dark, deep, glossy green foliage, form a never-tiring source of attraction, while the aromatic odour exhaled is of a grateful type. *O. trailii*, also another splendid species, but sparingly occurred. A list of the ferns and fern allies is given. *Todea superba* grows luxuriantly; one specimen was examined which had a stout stem some 18 feet high, from which arose a dense crown of nearly erect fronds, with drooping tips; some of these were several years old and were between four and five feet in length, of a deep blackish green. Mosses and large frondose Hepaticæ also abounded.

Mr. Cheeseman, Mr. Colenso, and Mr. Petrie, continue their descriptions of species new to science and to New Zealand.

In the section devoted to geology Capt. F. W. Hutton describes a large number of new Tertiary shells; Dr. J. von Haast has notes on the geological structure of the Southern Alps of New Zealand, in which he criticises Dr. Hector's recently-published map of this district; and Dr. Hector has a note on the geological structure of the Canterbury Mountains, in which he very temperately justifies changes in his views of geological periods as based on the progress of his knowledge of facts. Mr. James Parks's account of the ascent of Mount Franklin will be read with interest; though occupying a central position in the province of Nelson, it does not seem to have been before ascended. The Waiau Gorge is described as one of the most wonderful in New Zealand. On both sides the mountains frequently rise by a succession of steep, rugged precipices to a height of 3500 feet over the river. About 6050 feet high a small area of glacier ice was found, probably all that now remains of the great Waiau Glacier. Small patches of red snow were found; at 6500 feet in height permanent snow-fields were met with, and the top of the range, described as a mere razor-back, only a few feet wide, and composed of loose, angular, and slab-like rocks was found to be 7500 feet high. The highest peak, by aneroid measurement, was 350 feet higher. A list of the Alpine plants collected on the occasion, and determined by Mr. J. Buchanan, is appended.

It will be judged from this short notice that this volume, edited by Dr. Hector, is one coming in no way short of its predecessors and that it reflects credit on the scientific workers of New Zealand.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—A Fellowship will be filled up in Lincoln College in January next.

The Examination will be in the subjects of Animal Physiology and Animal Morphology; and candidates are invited to send in any treatises or theses that they may have written or published in special branches of one or both of these subjects.

Candidates should communicate at once with the Rector, who will furnish them with full information as to the conditions and tenure of the Fellowship.

CAMBRIDGE.—Another development from Prof. Stuart's School of Engineering is probable. The Special Board for Physics and Chemistry, considering the number of students of engineering warrants such a step, propose for their benefit an Honours Examination, to be connected with the Natural Sciences Tripos. Certain branches of Mathematics, useful alike for students of Engineering, Physics, and Chemistry, are to be introduced into an examination alternative with the first part of the Natural Sciences Tripos. Papers should be included on Principles of Measurement, Theory of Structures, Properties of Matter, Principles of Mechanism, and other branches of Physics and Chemistry, and there should be practical work in Engineering, as well as in Physics and Chemistry, each candidate being required to pass the practical examination in at least one of these three subjects. A student passing this examination with credit in his third year should be entitled to a degree in honours.

A second higher Examination is proposed, to be concurrent with the second part of the Natural Sciences Tripos, in the same subjects as above-mentioned, and the examiners should be at liberty to set questions involving the Mathematics of the first Examination, and in those parts of Mineralogy which belong to Physics and Chemistry. Other conditions are similar to those of the Natural Sciences Tripos. The Special Board for Mathematics has expressed its general approval of the scheme.

At St. John's College E. H. Hankin and F. S. Locke, both of St. Bartholomew's Hospital Medical School, have been elected to Exhibitions of 50*l*. a year in Natural Science. In Mathematics, F. M. Monro, King William's College, has been elected to a Foundation Scholarship of 80*l*. a year; A. G. Cooke, City of London School, to a Minor Scholarship of 75*l*. a year; A. Kahn, Middle Class School, Cowper Street, E.C., and J. A. Lawrenson, Liverpool Institute, to Minor Scholarships of 50*l*. a year; W. H. Box, University College, Aberystwith, and S. Humphries, Middle Class School, Cowper Street, E.C., to Exhibitions of 40*l*. a year for three years.

SCIENTIFIC SERIALS

The Journal of Anatomy and Physiology for October (vol. xx. part 1) contains:—On the anatomy of the muscles, ligaments, and fascia of the orbit, by C. B. Lockwood (plate 1).—Two cases of an abnormal coronary artery of the heart arising from the pulmonary artery, by Dr. H. St. John Brooks (plate 2).—On a second bursa connected with the insertion of the biceps, &c., by A. Ward Collins.—Abnormalities of the lobes of the human lung, by A. E. Maylard.—On the nature of ligaments, part 4, by J. Bland Sutton (plate 3).—Vital relations of micro-organisms to tissue elements, by Drs. G. S. Woodhead and A. W. Hare.—The blood-forming organs and blood-formation: an experimental research, part ii., by Dr. J. Lockhart Gibson.—The relationship of urea-formation to bile-secretion: an experimental research, by Dr. Noel-Paton.—The index of the pelvic brim as a basis of classification; and on the anatomy of Sowerby's whale, by Prof. W. Turner (plate 4).

The Quarterly Journal of Microscopical Science for October contains:—On the chromatology of the blood of some invertebrates, by Dr. C. A. MacMunn (plates 33 and 34). Among other pigments referred to, the colouring-matter of the perivisceral fluid of *Strongylocentrotus lividus*, named echinochrome, is described in detail.—On the cephalic appendages of the gymnosomatous Pteropoda, and especially of Clione, by Dr. Paul Pelseneer (plate 35). The cephalic appendages in Clione, Clionopsis, and Pneumodermon are described. In Clione there are tentacles, properly so called, and buccal cones. In Pneumodermon there are tentacles and two acetabuliferous buccal appendages, and in Clionopsis only tentacles are found. While the author leaves the function of the buccal cones in Clione doubtful, there can be no doubt as to the sucker-like functions of the appendages in Pneumodermon.—Evidence in favour of the view that the coxal gland of Limulus and of other Arachnida is a modified nephridium, by G. L. Gulland, M.A. (plate 36), with a note thereon by Prof. E. Ray Lankester, in which the following important statement is made:—"The space in the connective tissue into which the young nephridium opens internally is *not* a blood space. The blood system in the larger Arthropoda is altogether distinct from the general system of lacunæ of the connective tissue. The *lacunæ* form a *lymphatic system* which contains a liquid distinct from the blood: they represent the body cavity, and as such receive the internal openings of the nephridia."—Notes on the embryology of Limulus, by Dr. J. S. Kingsley (plates 37–39).—On the anatomy of the Madreporaria, part i., by G. Herbert Fowler, B.A. (plates 40–42).—The issue of the "Supplement" numbers of this journal being found inconvenient, it has been decided to publish its numbers for the future at such intervals as the accumulation of material renders desirable. Though more than four numbers will thus in all probability be published in the course of a year, the title will remain unaltered. Four numbers will make a volume.

Two papers are especially noteworthy in the *Journal of Botany* for November:—Rev. H. E. Fox and Mr. F. J. Hanbury's "Botanical Notes of a Tour in Caithness and Sutherland," where they had the opportunity of visiting large tracts of country from which botanists are, as a rule, now practically shut out, that they may not interfere with the sports of the owners; and Mr. F. N. Williams's careful "Enumeration of the Species and Varieties of *Dianthus*."

The number for December is signalised by a continuation of the record of Mr. Thos. Hick's important observations on protoplasmic continuity in the Fucaceæ. He has now detected this continuity in two other species, *Hemanthalea lorea* and *Laminaria digitata* (the latter not strictly belonging to the Fucaceæ), in the cortical and central, less certainly in the epidermal tissue. In the latter species the continuity is effected through the intervention of sieve-plates. Mr. James Britten gives a complete history of the important botanical collections made by Messrs. J. R. and G. Forster.

The Proceedings of the Linnean Society of New South Wales, vol. x. part 2, July 31, contains the following papers:—W. Macleay, revision of the genus Lamprina, and descriptions of new species; on two new Australian Lucanidæ; on new fishes from the Upper Murrumbidgee.—N. de Miklouho-Maclay, on the zoology of the Maclay coast, New Guinea, ii.; on two new species of Dorcopsis (plates 19 and 20); on the brain of *Halicore australis* (plate 24).—Dr. R. von Lendenfeld, on Australian sponges lately described by Carter; on a Medusa from the tropical Pacific.—A. G. Hamilton, on the fertilisation of *Goodenia hederacea* (plate 21).—K. H. Bennett, on the habits of *Falco subniger* and *Glareola grallaria*.—Rev. J. M. Curran, on the geology of Dubbo (plates 22 and 23).—Baron von Mueller, on a remarkable Haloragis from New South Wales.—A. S. Olliff, the Cucujidæ of Australia.—D. Ogilvy, description of new fishes.—E. P. Ramsay, notes on birds from New Guinea; on a new species of Collyriocincla.—G. F. Mathew, R.N., on the natural history of Claremont Islands; on the butterflies of Thursday Island.—W. A. Haswell, M.A., jottings from the biological laboratory of Sydney University.

Zeitschrift für wissenschaftliche Zoologie, Band 42, Heft 3, October 27.—On the movements of the foot in the Lamellibranchs, by Dr. A. Fleischmann (with five woodcuts).—On the oceanic fauna off the coast of New Guinea, by Dr. R. Greeff (plates 12–14). Rolas or Pigeon Island is separated from St. Thomas by a channel of from 3 to 4 km. wide. Under favourable winds, shoals of larval and mature Crustacea, Mollusca, Echinoderm larva, Medusa, Radiolaria, &c., float through. The general description of the place is most alluring; surely the proprietor, Mr. F. José de Araujo is in the possession of an earthly paradise for a marine zoologist. In this memoir Dr. Greeff describes and figures several new species of Tomopteris and Alciope, giving, at the same time, anatomical details.—Contributions to the anatomy and histology of *Priapulus caudatus*, Lam., and *Halicryptus spinulosus*, V. Sieb., by Dr. W. Apel (plates 15–17).—Contributions to our knowledge of the Mallophaga, by Dr. F. Grosse (plate 18). These researches are chiefly based on a remarkable new parasite from a pelican found by Dr. Reiss in Chili, which is described as belonging to a new genus and species (*Tetrophthalmus chilensis*).—On the reproductive organs in *Nematois metallicus*, Pod., by N. Cholodkovsky (plate 19), a memoir of importance to the Lepidopterist.

Archives Italiennes de Biologie, tome vi. fasc. 2, March 31, contains:—Clinical and physiological researches on paraldehyde, by Dr. V. Cervello.—On the physiological action of antipyrene, by Dr. F. Coppola.—On perimetry, and on self-registering perimeters, by Dr. Ferri.—On the effects of salt on Cercaria, by Prof. E. Perroncito.—On cicatrisation after wounds in the kidney; and on the partial regeneration of that organ, by G. Pisenti (plate).—On albumen in the saliva, and the bile in albuminuria, by Matilda Dessalles.—On the minute structure of the air-sacs in birds, by Dr. E. Ficalbi (abstract).—On anomalies in the number of the semi-lunar, aortic, and pulmonary valves, by G. Martinotti, and G. Sperino.—On microphytes in the normal human epidermis, by Prof. G. Bizzozero (from *Virchow's Archiv*), December, 1884 (plate).—On the organ of Corti in the Cercopitheci, by Prof. A. Tafani (illustrated).—Notes on the anatomy of a negro (iii.), by Prof. Giacomini (plates).

THE October number of the *Nuovo Giornale Botanico Italiano* contains only two original papers:—On the Bryology of the neighbourhood of Cuneo, by Sig. Macchiati; and On the nature and development of the integuments of the seed in *Tilia*, by Sig. Mattirolo. These integuments may be classified into two layers, the inner of which displays the light line characteristic of the genus *Tilia*, and which is due to the formation of lignin.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 17.—"A New Form of Spectroscope." By J. Norman Lockyer, F.R.S.

Some two or three years ago, when the sun-spot work carried on at Kensington revealed the different behaviour, in different spots, of lines visible in the spectra of the same element, it seemed desirable to extend similar observations to metallic prominences, and, if possible, in such a way that comparisons over a considerable reach of spectrum should be secured.

It then struck me that a grating cut in half, with one part movable, would afford a ready means of doing this.

Circumstances prevented the realisation of this scheme till quite recently, when I put into Mr. Hilger's hands a grating presented to me by Mr. Rutherfurd.

The result is excellent. It is possible to observe C and F, for instance, together, quite conveniently, with either a normal or a tangential slit. The only precautions necessary are to see that one-half of the light passing through the object-glass falls on one-half of the grating, and that the rays which come to a focus on the slit plate are those the wave-length of which is half way between the wave-lengths compared.

Linnean Society, December 17.—Mr. Frank Crisp, LL.B., Vice-President and Treasurer, in the chair.—*Heritiera littoralis*, var. *macrophylla*, Dr. Masters showed a branch with leaves and fruit, received from Prof. Cornu, of the Jardin des Plantes, Paris. The adult leaves, of very large size, are dark green above, and silvery white beneath. The latter, due to an investment of shining, peltate, membranous scales, has given rise to the name "Looking-glass tree." This Sterculaceous tree is a native of the tropics of the Old World, in the vicinity of coasts, and occurs inland in the hills of Eastern Bengal. Kurz considered the species and its variety as quite distinct, a view not held by Dr. Masters.—Mr. Charles Stewart exhibited the stridulating organ of a Spiny Lobster (*Palinurus*); he showed under the microscope the file-like bow and its two tubercles, also, by means of a softened specimen attached to the carapace, he produced the peculiar grating noise which the animal makes during life.—Mr. J. G. Baker exhibited specimens of *Lycopodium complanatum*, collected by the Rev. A. Lawson on the Somersetshire side of Exmoor, near Porlock, thus corroborating those who have ascribed a British habitat to the species in question.—Mr. Clement Reid drew attention to a series of fossil seeds and plants from the "Forest Bed" of the Cromer district, Norfolk; their very excellent state of preservation enabled their comparisons with living plants to be easily made out, and thus a clue given to the history of our present flora.—Mr. Thos. Christy exhibited a plant of *Angræcum sesquipedale* in flower, and a plant of *Catasetum purum*, showing flowers erect and reversed in the same spike. In none of the flowers was the ovary visibly twisted, but in long ovaried orchids it is often very difficult to detect the twisting of the ovary by the external aspect. This specimen illustrated the fact that light or the absence of light was not the cause of the alteration of position.—The following specimens were exhibited from Mr. E. M. Holmes, viz. :—(1) *Ustilago marina*, Dur., a fungus new to Britain, having been discovered by Mr. Holmes, last autumn, growing on *Scirpus parvulus* at Studland Bay, Dorset, on ground covered by brackish water; (2) fruit of *Afzelia cuanzensis* from Limpopo, Natal, sent him as the pod of a mahogany-tree; (3) fruit of *Trichilia Dregei*, from the same district,—oil is obtained from the seeds by boiling, and with this insecticide the Kaffirs anoint their bodies.—Mr. F. R. Cheshire gave an epitome of his late researches on the tongue of the bee, describing the structure and mode in which he believes suction of nectar takes place.—A paper was read, on Entomostraca collected by Mr. A. Haly in Ceylon, by Prof. G. S. Brady. The freshwater forms were obtained at Colombo; the marine species were dredged at a depth of two fathoms in the Gulf of Manaar. The freshwater Copepoda and Cladocera approach well-known European species. Among the Ostracoda is a curious new generic form, *Cyprinotes*. Additional information is also given by the author respecting *Cypris cylindrica* (*Malcolmsonia*) and *C. subglobosa*.—Mr. H. N. Ridley read a paper on orchids from Madagascar. The collection (fifty in number) was obtained by Mr. Fox in the neighbourhood of Imerina. Among them are three genera new to the flora of the island, viz. *Arnottia*, indigenous to the Mauritius; *Brownleea*, hitherto only known from South Africa; *Holothrix*, an East African representative. Another interesting novelty is *Satyrium gigas*.—Two other papers, read in abstract, were: a monographic revision of the recent Ephemeridæ, part iv., by the Rev. A. Eaton; and Colombian species of the genus *Diabrotica*, part ii., by Mr. Joseph Baly.

Anthropological Institute, December 8.—Mr. Francis Galton, F.R.S., President, in the chair.—Mr. H. H. Johnston exhibited a collection of photographs of African natives and scenery.—Mr. H. W. Seton-Karr exhibited a number of photographs of North American Indians, taken by him during his recent visit to Canada.—Mr. Joseph Hatton exhibited several ethnological objects collected by his son, the late Frank Hatton, in North Borneo. Mr. W. M. Crocker also exhibited some objects from Borneo; and Mr. R. Meldola exhibited some photographs of Nicobarese.—A paper by Mr. E. H. Man, on the Nicobar Islanders, was read, in which the author described the wild race inhabiting the interior of Great Nicobar and called by the inhabitants of the other islands of the group "Shom Pen." It appears certain that they are the descendants of a very ancient aboriginal population of Mongolian origin. The height of the males appears to range between 5 feet 2 inches and 5 feet 8 inches; their skin is fairer than that of the generality of the coast people, who on their part are less dark than the Malays; the hair is straight, and is commonly worn uncut and unkempt. Their dwellings are small and erected on posts; the floors being raised six or seven feet above the ground necessitates the use of ladders. Mr. Man hopes before long to be able to supplement in many particulars the meagre information that has hitherto been obtainable regarding the Pen, but the task is one of considerable difficulty.

Royal Meteorological Society, December 16.—Mr. R. H. Scott, F.R.S., President, in the chair.—Mr. J. Hartnup, Mr. A. W. Preston, Mr. R. Sheward, and Mr. W. B. Worthington were elected Fellows of the Society.—The following papers were read:—On the influence of forests upon climate, by Dr. A. Woeikof, Hon.Mem.R.Met.Soc. The first step towards a scientific investigation of the influence of forests upon climate was taken by the establishment of the Bavarian Forest Meteorological Stations. This example was followed by Germany, France, Switzerland, Italy, and other countries. As a general result it was found that during the warmer season the air and earth temperatures were lower in the forest, as compared with contiguous woodless places; that their variations were less; and that the relative humidity was greater. Dr. Woeikof's discussion of this question shows that in the western portions of the Old World extensive forests materially influence the temperature of neighbouring localities, and that the normal increase of temperature from the Atlantic Ocean towards the interior of the Continent is not only interrupted by their agency, but they cause the summer to be cooler in regions situated further in the interior than those nearer the sea. Hence, forests exert an influence on climate which does not cease at their borders, but is felt over a greater or less district, according to the size, kind, and position of the forests. From this it naturally follows that man, by clearing forests in one place and planting others in another, may considerably affect the climate.—Report on the phenological observations for 1885, by the Rev. T. A. Preston, M.A., F.R.Met.Soc. The year has been a very dry one, and this has acted in such a manner on vegetation that, although the winter was mild, plants were very late in flowering, and lasted only a short time. The bloom was often profuse, and, as bees and other insects could visit them, the crop of fruit was unusually great—the apples, for instance, being often spoilt in quality from the enormous number on the trees; whilst in the case of wild fruits the brilliant colour of the bushes when in fruit was quite as beautiful as when in bloom. But at the same time the drought acted very prejudicially, especially to root-crops and bush-fruit, as well as strawberries. In the case of the root-crops, the seed had great difficulty in germinating, and the weak plants were at once overpowered by insect pests, so that the crops of turnips were generally complete failures. The insect pests also did much damage to bush-fruit, while the drought prevented the strawberries from swelling. The corn did not suffer to any great extent, the dry season allowing the land to be prepared: and, although the straw was often short, the yield was not unsatisfactory. A general absence of butterflies was noticed in some places. In the south of England the white butterflies were most abundant at one time, but the autumn butterflies were not so plentiful as usual.—Etudes sur les crépuscules rosées, by Prof. A. Ricco, of Palermo.—The storm of October 15, 1885, at Partenkirchen, Bavaria, by Col. M. F. Ward, F.R.Met.Soc. This was the most destructive storm which has occurred in this valley since the winter of 1821–22. The storm burst suddenly at 7 p.m., and lasted about half an hour, but in that short period nearly every house was unroofed, and it is computed that in one forest alone above 250,000 trees were laid prostrate.

Geological Society, December 2.—Prof. T. G. Bonney, F.R.S., President, in the chair.—Charles Dawson, Francis J. Ede, Lewis Edmunds, Henry A. Gordon, George Frederick Harris, Samuel Learoyd, John Main, Mansfeldt Henry Mills, Rev. Thomas Randell, James Radcliffe, Andrew Edmund Castlestuart Stuart, Tudor Gruffydd Trevor, and Arthur Smith Woodward were elected Fellows of the Society.—The following communications were read:—On some borings in Kent; a contribution to the deep-seated geology of the London Basin, by W. Whitaker, B.A. (Communicated by permission of the Director-General of the Geological Survey.) Seven deep borings in the eastern part of Kent were described, all of them reaching to the Gault. The chief one is at Chatham Dockyard, where, after passing through the whole thickness of the Chalk, the Gault was found to be 193 feet thick, whilst the Lower Greensand was only 41 feet, and was underlain by Oxford Clay, a formation not before known in Kent. These parts involve the thinning of the Lower Greensand from 200 feet at the outcrop a few miles to the south, and the entire loss of the whole of the Wealden series, which, further south, exists in great force, the Weald Clay being 600 feet thick, or perhaps more, and the Hastings Beds 700 feet or more. Still further south, in the central part of the Wealden district, there are outcrops of the Purbeck Beds, whilst the Subwealden boring continues the series downwards. We have thus an addition to the beds wanting at Chatham of some 400 feet of Purbeck and Portlandian, of over 1100 feet of Kimeridgian, and of nearly 500 feet of Corallian, &c. In a section of 32 miles, therefore (the distance between the Subwealden and the Chatham borings), we have a thinning of beds to the extent of over 3400 feet, or at the average rate of about 100 feet in a mile. This northerly thinning agrees with the facts that have been brought before us from other deep borings in and near London; but the Chatham boring is the first in the London Basin in which a Middle Jurassic formation has been found. The teaching of the deep borings, as a whole, is that north of the Thames older rocks rise up beneath the Cretaceous beds, whilst on the south newer rocks come in between the two. The question of the finding of the Coal-measures beneath parts of the London Basin seems to admit of a hopeful answer, whilst the lesson of the deep borings as regards water-supply is that there is small chance of getting water from the Lower Greensand at great depths underground. It would be well if underground exploration could be conducted on a systematic plan, with proper regard to both topographical and geological considerations, and not left any longer to the chance work of people in search of water.—Note on some recent openings in the Liassic and Oolitic rocks of Fawler in Oxfordshire, and on the arrangement of those rocks near Charlbury, by F. A. Bather; communicated by Prof. J. Prestwich, F.R.S. The River Evenlode rises in the Lower Lias of the Vale of Moreton, traverses the range of Oolites, and joins the Isis opposite Wytham Mill. Lias is exposed to about three-quarters of a mile below Fawler, where Great Oolite is brought down by a fault; and in the Geological Survey map Lower Lias is brought down the valley to within half a mile of Charlbury railway station. In this paper the author gives reasons for believing that the distribution of the different beds constituting the Lias in the Evenlode Valley do not agree with the Geological Survey map, nor with Prof. Hull's description; recent sections and borings made for clay, used in brick- and pottery-making, having exposed Lower Lias clay in a brick-yard at Fawler, Marlstone and Upper Lias clay in a neighbouring coombe, and in a long section 100 yards north of the brick-yard Inferior Oolite comes in upon the Upper Lias clay. On examining the banks of the Evenlode, north of Charlbury, it was found that clays referred in the Survey map to Lower Lias are really Upper Liassic, being above the Marlstone, sections of which are exposed near Culsham Bridge. It was shown how these corrections in the mapping of the ground are explained by the section along the line of the Evenlode and by the dips of the beds.

Royal Microscopical Society, December 9.—A. D. Michael, F.L.S., Vice-President, in the chair.—Mr. Swift's large photo-micrograph of the tongue of the blow-fly, which had obtained the prize medal at the recent Exhibition of the Photographic Society, was exhibited. The plan adopted was to take an enlarged photograph from a small image obtained by a paraffin lamp by artificially strengthening the image where required.—Mr. Crisp exhibited Prof. Klein's microscope for observing crystals when heated to a high temperature; also an apparatus for enabling four photo-micrographs to be taken of the same object, so as to give a different length of exposure to each or to photograph different parts of an object rapidly.—Dr. Maddox exhibited a series of photographs of inked surfaces covering pencil lines. Mr. Crisp referred to a curious case in which a forger wanted to add some words to a bond which had been originally written with very pale ink. The added words were darker, and he therefore retraced the whole of the original writing to make it look all alike, but examination with the microscope at once detected the forgery.—Dr. E. Crookshank read a paper on the cultivation of bacteria, which he illustrated by numerous drawings and by a series of preparations. He also exhibited and described a collection of apparatus of the latest and most approved construction for the cultivation of bacteria and the preparation of the media employed.—Mr. Robertson described a method of preparing a section of spinal cord by soaking in picrocarmine before cutting.—Mr. Meates's note on a new highly-refractive medium for mounting sulphide of arsenic was read.—Mr. Cheshire read a paper on the pulvillus of the bee, calling attention to a notch found upon the leg of the bee, and explaining what he considered to be its function as opposed to the explanations given by some other observers.—Mr. J. W. Groves exhibited some mounted sections cut by the large Barrett microtome to show how large good sections could be made with the machine.—Eleven new Fellows were elected and proposed.

DUBLIN

Royal Society, November 18.—Physical and Experimental Science Section.—Prof. W. F. Barrett in the chair.—On the beryls and iolite of Glencullen, co. Dublin, by J. Joly, B.E. The beryls of Glencullen, while presenting the angles and faces of normal beryl, are found, on microscopic examination, to consist of a mixture of beryl and orthoclase. The latter mineral amounts sometimes to 72 per cent. of the entire crystal. There is evidence that this phenomenon was produced by alteration, not by inter-crystallisation in the first instance. The orthoclase contains much iolite in sharp well-defined crystals. The beryls of the Dublin granite lose all colour when heated for a few days to a temperature of about 300° C. An hour's heating at 350° C. deprives them of colour. The bearing of this phenomenon on the history of the granite is pointed out by the author.—On the absolute weights of the chemical atoms, by G. J. Stoney, D.Sc., F.R.S.—On a new form of instrument for determining the magnitudes and colours of stars, by John Ballot; communicated by Howard Grubb, M.E., F.R.S. The apparatus consists of an arrangement attachable to the draw-tube of a telescope, by means of which an image of small illuminated apertures can be thrown into the field of the eye-piece and viewed by an observer at the same time as the image of the star formed by the objective. The light is supplied by a small incandescent Swan's light condensed by a reflector, and is passed through four sets of slides or revolving wheels, the first containing a wedge of neutral-tinted glass, the second a set of microscopic apertures of varying sizes, and the third and fourth sets of seven coloured glasses. By those four slides it is possible to regulate the size, colour, and intensity of the ghost-star, and thus form a standard by which the magnitude and colour of any star can be determined. The two coloured slides are supplied in order that secondary tints may be obtained by combination of any two primary colours. The accuracy of the instrument depends of course on the constancy of the lamp. This constancy can be obtained, within moderate limits, by proper electrical contrivances, but reference should occasionally be made to standard stars. Even though the source of light be not absolutely constant, it appears probable that a better result will be obtainable by such an apparatus than by any in which the constancy of sensitiveness of the human eye has to be depended upon from observation to observation.—Thomas Edmondson exhibited the new circular calculating-machine invented by Joseph Edmondson, Halifax.—Howard Grubb exhibited Wilson's new sunshine-recorder.

Natural Science Section.—Presidential Address to the Royal Geological Society of Ireland by Prof. J. P. O'Reilly, C.E., M.R.I.A., &c.—Note on *Halcampa chrysanthellum*, Peach, by Prof. A. C. Haddon. A full and critical note on this species, which is shown to embrace *H. vittata*, Kef., *H. bilateralis*, Kef., *H. kefersteini*, Andr., and *H. adresii*, Hadd.—On certain sense-organs occupying the perforations in the shell of the Brachiopoda, by Prof. Sollas, D.Sc., &c. The cæcal processes occupying the canals in the Brachiopod shell are extensions of the outer epithelium of the mantle. At the outer end, which lies immediately beneath the chitinous periostracum, each terminates in a large cell with a large nucleus and nucleolus, invested by other smaller cells. The large cell is continued into a nerve-fibril, which runs axially down the cæcal process, and enters the nervous layer of the mantle. This is the structure of a sensory end-organ, which in this case seems to transfer luminous radiations.—Additional note on *Macrozamia denisonii*, by Prof. W. R. McNab, M.D. This Cycad, known in gardens as *M. denisonii*, but which botanically is *M. perowskiana*, Miguel, has recently produced a fine female cone in the Royal Botanic Garden, Glasnavin, and was noticed at the June meeting of the Society. The cone was cut on September 1, and shows in a very beautiful manner the close series of small sterile scales which form the whole base of the sessile cone. Although the cone looked a terminal structure, it forms a lateral branch, and now (November) the young leaves are developing from the growing axis.—On New Zealand Coleoptera, by D. Sharp, M.B. No beetles from New Zealand were known to Linnæus, and up to 1867 about 150 species had been noted; now about 1500 species are known to the author, who estimates that the Coleoptera of New Zealand will probably number from 3000 to 3500. In the present paper a special scrutiny is made of the Pterostichini and Otiorhynchini. The Coleopterous fauna is analogous to that of Europe and other continental regions, but contains a large proportion of forms which are to be regarded as little evoluted. Cetoniadæ are wanting, and the Buprestidæ are represented by two minute and obscure forms. The Phytophaga, which, like the two preceding groups are remarkable for the brilliancy of their colouring, are few in number, small in size, and dull coloured. So also with the weevils. There are no Longicornes with tufted antennæ, and no horned Lamellicornes. The Coleopterous fauna is remarkable for the number of isolated forms which have little or no connection with the ordinary forms of the island. The Coleopterous fauna of New Zealand seems to have most affinity with that of Chili and Patagonia, and but little with the Australian fauna, many of the most characteristic Australian forms being wholly unrepresented in New Zealand.

SYDNEY

Royal Society of New South Wales, August 5.—Prof. Liversidge, F.R.S., President, in the chair.—The Rev. P. MacPherson, M.A., read a paper on some causes of the decay of the Australian forests. Photographs of a tree near the Lane Cove Road, which measured about 25 feet in circumference at a height of 30 feet from the ground, were shown by Mr. H. C. Russell, B.A. He thought that such a rare relic of a past era in the forest-growths of Australia should not be lost, and moved that the Government be asked to reserve the ground on which it stands.

PARIS

Academy of Sciences, December 14.—M. Jurien de la Gravière, Vice-President, in the chair.—Movements of the molecules of the so-called "solitary wave" propagated on the surface waters of a canal (continued), by M. de Saint-Venant.—On a method of analysis applicable to the study of the hydrocarburet mixtures of the aromatic series, by MM. C. Friedel and J. M. Crafts. By the process here described all the four isomeric bodies answering to the formula C_8H_{10} (ethylbenzene and the three xylenes) become transformed to substances as easily separable as most bodies dealt with in mineral analysis. Not only is this effected without loss of matter, but the combinations when finally analysed are found to possess from five to seven times the weight of the hydrocarburet used in the analysis.—Remarks on the new specimens recently deposited in the Palæontological Department of the Museum, by M. Albert Gaudry. Amongst these is the entire skeleton of a fossil edentate (*Scelidotherium leptocephalum*) from the Buenos Ayres district, apparently a contemporary of the Megatherium and Glyptodon; also a remarkably well-preserved Mystriosaurus, and castings of a New Zealand Megalania, of a Russian Elasmotherium, and of some Dinoceras from the Rocky Mountains.—Claim of priority for the use of the sulphate of copper against brown rust vindicated for M. Benedict Prevost, by M. de Lacaze-Duthiers.—On a new theory of algebraic forms, by Prof. Sylvester.—On the propagation of the movement in an indefinite fluid (second part), by M. Hugoniot.—Remarks on the *Annuaire* for the year 1886, presented to the Academy on behalf of the Bureau des Longitudes, by M. Faye.—Remarks on MM. Faudel and Bleicher's "Materials for the Study of Prehistoric Alsace," presented by M. Hirn.—Observations of Fabry's comet and of Barnard's comet made at the Observatory of Algiers with the 0·50m. telescope, by M. Trépied.—Observations of Barnard's new comet made at the Paris Observatory equatorial of the West Tower), by M. G. Bigourdan.—Note on the construction of the large double-meridian circles, by M. Gruey.—On a new class of integrable linear differential equations, by M. Halphen.—On a new method of generating unicursal algebraic curves, by M. G. Fouret.—On the movement of a point in a plane and on imaginary time, by M. L. Lecornu.—On certain geometrical surfaces of the third order possessing an infinite number of umbilici, by M. A. de Saint-Germain.—On the construction of machines intended for the electric transmission of power in connection with the electric machines at present working between Creil and Paris, by M. Marcel Deprez.—An inquiry into the causes that have momentarily arrested the experiments on the transmission of power between Creil and Paris, by M. A. Sartiaux. The accident, the first recorded for over a month, was shown to be caused by defective isolation along the line of transport resulting from accidental communications with the earth, which may easily be avoided in future.—Note on the relations existing between the absorption of light and the emission of phosphorescence in compounds of uranium, by M. H. Becquerel. The molecular state of these compounds causes them to exercise on light an elective absorption of harmonic radiations, while some of them emit by phosphorescence inferior harmonic luminous radiations of the absorbed rays. The absorption seems due to vibratory motions caused by the influence of the incident radiations, and apparently synchronous with the absorbed rays.—Spectrum of the nitrogen bands: its origin, one illustration, by M. H. Deslandres. With the aid of M. Cornu's photographic apparatus, the author has determined beyond all doubt the origin of a whole group of these ultra-violet bands, which form the spectrum of a nitrogen and oxygen compound, so far confirming Angström's well-known view.—Note on the diffusion of heat, by M. Léon Godard.—A study of the hydrates of arsenic acid ($AsO_5,3HO$, and $AsO_5,2HO$), by M. A. Joly.—Researches on the formation of the vast deposits of nitrate of soda in certain parts of South America, by M. A. Müntz. This nitrate appears to be the result of a double decomposition between the nitrate of lime and marine salt. But it was not formed in the places it at present occupies, where it has been gradually concentrated under divers outward influences.—Fresh researches on the various compounds of proteine, by M. Paul Schutzenberger.—Note on the preparation of benzoylcyanacetic ether and of cyanacetophenone, by M. Haller.—On the accumulation of nitrogen in ground kept constantly under grass, by M. P. P. Dehérain.—Note on a microbe whose presence seems to be connected with the development of rabies, by M. H. Fol.—On the construction of the jaw-bones of vertebrate animals, by M. A. Lavocat.—On the development of the basin in the cetaceans, by M. H. P. Gervais.—On the development of the horny layer in the gizzard of poultry, and of the glands secreting it, by M. Maurice Cazin.—On the development of the tonsils in mammalians, by M. Retterer.—Researches on the comparative anatomy and physiology of the trigeminal, facial, and cephalic sympathetic nerves in birds, by M. Laffont.—Remarks on two species of Balanoglossus (*B. hacksi*, from Japan, and *B. talaboti*, from the district of Marseilles), by M. A. F. Marion.—On the skeleton of the extinct genus Scelidotherium, recently deposited in the Paris Natural History Museum, by M. P. Fischer.—On the action of chlorophyll on the carbonic acid outside the vegetable cell, by M. P. Regnard.—Note on the stratigraphic structure of the Menez Hills, Brittany, by M. Charles Barrois.—A chemical study of the substances brought up during the soundings of the *Travailleur* and *Talisman* Expeditions: constant presence of copper and zinc in these deposits, by M. Dieulafait.—On the non-nitrous or slightly nitrous diet usually recommended in the case of diabetes, by M. Boucheron.—Note on some fresh documents advanced to support the theory of a cosmic origin of the late crepuscular glows, by M. José J. Landerer.

TERTIARY VERTEBRATA OF THE WEST

Report of the United States Geological Survey of the Territories. F. V. Hayden, United States Geologist-in-Charge. Vol. III. "The Vertebrata of the Tertiary Formations of the West." Book I. By Edward D. Cope. (Washington, 1883-1884.)

THE American Government has in many ways shown the importance which it attaches to the diffusion of scientific knowledge; but in nothing has this been more clearly seen than in the care with which the results of the Geological Surveys have been published, and the liberality with which these works have been distributed; so that geologists on this side of the Atlantic are well acquainted with the magnificent quarto volumes in which the Reports of the Geological Survey of the Territories have been published. A number of these volumes had already appeared under the directorship of Dr. F. V. Hayden, when, in the year 1882, their publication was committed to the charge of Major J. W. Powell, Director of the United States Geological Survey. The work now before us is the first Report of the Survey of the Territories published since this change, and will take its place as the third volume of the series. While fully equal to the previous reports in the care bestowed upon the drawing and printing, it is by far the largest volume which has yet appeared, comprising, as it does, more than a thousand pages of letterpress and upwards of one hundred lithographic plates.

Prof. Cope began this work in 1872, and since then it has been carried on both in the field and in the study. It was originally intended that the Vertebrata of the "Cenozoic" and "Mesozoic" formations should form the third and fourth volumes of the Reports, but such a large amount of material has been obtained that it has become necessary to limit the work to the description of the "Cenozoic" Vertebrata, and this is to be divided into four parts, thus:—

Part I. Puerco, Wasatch, and Bridger Faunæ (Eocene).

Part II. White River and John Day Faunæ (Low. and Mid. Miocene).

Part III. Ticholeptus and Loup Fork Faunæ (Upper Miocene).

Part IV. Pliocene.

The present volume includes Part I. and Part II. as far as the Carnivora, the number of species described being 349, included in 125 genera, no less than 317 species having been determined by Prof. Cope.

The explorations, resulting in the acquisition of this splendid series of fossil Vertebrata, were conducted chiefly by the author himself, assisted by an efficient staff, and were carried on with much trouble and personal risk, not only on account of the inhospitable country in which part of the explorations had to be made, but also because of the hostility of the Cheyenne Indians, who, in certain regions, were during this time continually committing depredations and murders. No little credit is due to Prof. Cope and his able coadjutors for the manner in which this work was carried to so successful an issue in the face of many difficulties.

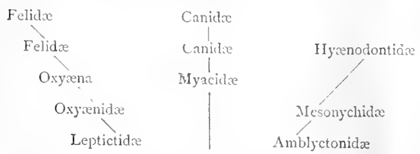
Before entering upon the description of the fossils, a short account is given of the Tertiary formations in which they were found, and an interesting and valuable comparison is made with the strata of the same age in Europe. A significant circumstance, with which geologists are to some extent already familiar, is the different story, regarding the age of these beds, told by the plants and mammals. The determination of the age of the formations known as the Loup Fork, White River, Bridger, Wasatch, Green River, and Laramie Beds, arrived at by Prof. Cope from a study of their higher vertebrate faunæ, does not agree with the conclusions of Mr. Lesquereux derived from his examination of the plant remains. The table given at p. 44 shows, in each case, the Flora a whole period in advance of the Vertebrata; for example, while the Laramie plants have an Eocene facies, the Vertebrata indicate an Upper Cretaceous age; and the fauna and flora of each of the other formations show a similar discrepancy.

The numerous *Bulletins* and reprints with which Prof. Cope has liberally supplied us during the last few years have made us to some extent acquainted with the progress of the laborious task which he has undertaken, and with the names proposed for some of the new types of animals which have been discovered. Even with this knowledge, however, one is perplexed, on first opening the book, with the array of new names. The overwhelming amount of material which had to be dealt with, including such a multitude of new forms, no doubt made it necessary to establish many new genera and species, and these would require, in some instances, to be placed in new groups; but, notwithstanding this, it will probably be felt by many palæontologists that it would have been better in some instances to extend the limits of a group rather than to make new ones. Be that as it may, Prof. Cope has laid us under no little obligation by giving us such a clear and systematic account of his herculean labours.

In the author's preface he touches upon the troublesome question of the rules of nomenclature. While agreeing with the law of priority, as generally understood, he gives half a dozen rules which have been adopted by a number of American biologists. The main principle underlying all these rules is, that a generic or specific name given by any author, without a sufficient description or definition, is not entitled to recognition by subsequent writers. To this principle no naturalist will be likely to take exception; but, unfortunately, the manner in which this rule has been applied by some authors has produced a result which it is most desirable to prevent, that is, an unnecessary multiplication of names. To take an instance, a writer (A.) describes a number of new species, giving them a generic name, without any definition, and, to quote Prof. Cope, "In these cases it is left to the reader (B.) to discover their characters. Should he do so, he becomes the real discoverer of the genus, and, as such, is entitled to name it." No doubt Mr. A. should have characterised his genus, and his name is *not entitled to be received;* but if Mr. B. is a true man of science, he will forego his right and "habilitate the *nomen nudum*," rather than burden his brother-workers with another addition to their load of synonyms, which is already a burden almost too heavy to be borne.

This volume is essentially a detailed description of genera and species, and as such is an extensive and invaluable mine of information, wherein palæontologists may work with profit for many years to come. But besides the more special descriptions, there is much of deep interest to the naturalist and evolutionist, a flood of light being thrown on the early Eocene forms, which were probably the progenitors of our existing mammals.

The Saurian genus *Champsosaurus*, hitherto known only from Cretaceous deposits, has now been found in the Puerco Tertiary series. The remarkable marsupial genus *Plagiaulax*, was originally described by Falconer from British Purbeck beds; within the last few years an almost identical genus has been met with in Tertiary strata in France; and now closely allied forms are made known to us from the American Tertiary groups. It is, however, among the higher mammalia that the most remarkable discoveries have been made. The finding of forms, less specialised than those living at the present day, has enabled Prof. Cope to trace what he believes to be the line of descent of some of the groups of living mammals. The determination of the characters of a considerable number of new genera and species, more or less closely allied to the *Insectivora*, has led to a new classification. It is proposed to include in a new order, called the *Bunotheria*, the sub-orders:—(1) *Creodonta*, (2) *Mesodonta*, (3) *Insectivora*, (4) *Tillodonta*, (5) *Tæniodonta*, and (6) *Prosimiæ?* The *Creodonta* come nearest to the *Carnivora*, while the *Prosimiæ* come nearer to the *Quadrumana*, groups (4) and (5) being distinguished by the possession of incisor teeth with persistent pulps. It is among the Eocene *Creodonta* that Prof. Cope finds the ancestors of the *Felidæ* and *Canidæ*. "In distinguishing between the ancestors of the *Felidæ* and *Canidæ*, we naturally seek to recognise in each an anticipation of the leading characters in the dentition which distinguish those families to-day" (p. 263). In the *Felidæ* we should expect a gradual abbreviation of the true molar series from behind. The *Canidæ*, on the other hand, not only retain the true molars, but have them also of a tubercular character. "Estimated by these tests the *Myacidæ* are clearly the forerunners of the *Canidæ*, and the *Oxyænidæ* of the *Felidæ*." The following diagram will show the families through which these relations are traced (p. 264):—



Unfortunately the new names prevent our fully appreciating these affinities, which can only be properly understood when the characters of these groups have been carefully studied. The forms allied to *Canis* which have been met with in the Lower and Middle Miocene are all said to be generically distinct from *Canis*, while those from the Upper Miocene pertain to the same genus The many new species of *Carnivora* have suggested to Prof. Cope a new grouping for the *Fissipedia*. These are in the first place divided into two subdivisions:—

(1) "External nostril occupied by the complex maxilloturbinal bone; ethmoturbinals confined to the posterior part of the nasal fossa; the inferior ethmoturbinal of reduced size . . . *Hypomyceteri*.

(2) "External nostril occupied by the inferior ethmoturbinal and the reduced maxilloturbinal . . . . *Epimyceteri*."

No. 1 includes the families *Cercoleptidæ*, *Procyonidæ*, *Mustelidæ*, *Æluridæ*, *Ursidæ*, *Canidæ*.

No. 2 the *Protelidæ*, *Arctictidæ*, *Viverridæ*, *Cynictidæ*, *Suricatidæ*, *Cryptoproctidæ*, *Nimravidæ*, *Felidæ*, *Hyænidæ*.

The species of *Carnivora* described are from the Miocene, and are all referable to the *Canidæ* and *Nimravidæ*, the first being divided into eight genera, all of which are represented except *Canis*; they have much resemblance to our dogs and foxes, and are separated chiefly by the modifications of their teeth. The second includes nine extinct genera, all closely allied to the *Felidæ*, but differing in having an alisphænoid canal and post-glenoid foramen. In some of them the dental formula is the same as that of the *Felidæ*; but in others there is an increase in the number of the molars and premolars. It is these variations which are used as generic distinctions. Some of the genera, such as *Pogonodon*, have the canine teeth so largely developed as to make a near approach to the sabre-toothed tigers.

The changes which are proposed in the names and grouping of the herbivorous animals are not less numerous or less radical than those among the flesh-eaters, to which allusion has been made above. The order *Ungulata*, as it is now generally understood, is to be divided into four orders, founded on characters of the carpus and tarsus; these are as follows:—

(1) *Taxeopoda* (including sub-orders *Hyracoidea*, *Condylarthra*, and *Toxodontia* ?).

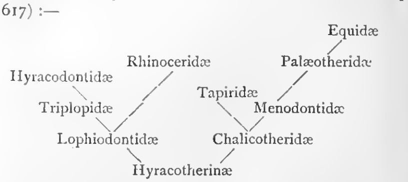
(2) *Proboscidea*.

(3) *Amblypoda* (including *Pantodonta*, *Dinocerata*, and *Talligrada*).

(4) *Diplarthra* (including *Perissodactyla* and *Artiodactyla*).

The necessity for some modification of this classification is already pointed out by Prof. Cope himself, for on p. 383, in speaking of the almost perfect skeletons of *Phenacodus primævus* and *P. Vortmani*, which genus is placed in the *Condylarthra* (Order 1), he says:—"The unexpected result is, that this genus must be placed in a special group of an order which includes also the *Proboscidea*."

Not the least important outcome of these discoveries in the Eocene deposits is the reconstruction, from numerous specimens, of the genus *Hyracotherium*; and consequent upon this the knowledge that it is, as Prof. Cope thinks, the earliest ancestor of the *Perissodactyla*. The following genealogical tree will show this relationship (p. 617):—



The *Hyracotherinæ* are here made the parent stock from which are supposed to have arisen, on the one side, the horses, through the Palæotheria; the tapirs being an offshoot from an ancient group, the Chalicotheridæ. On the other side the rhinoceroses have arisen from the Lophiodonts, from which also the Hyracodonts are to be traced.

Time alone will show whether the systems of classification proposed by Prof. Cope are founded on sufficiently important characters to render them permanent. It is probable that naturalists will hesitate before accepting such sweeping changes, especially as they necessitate the adoption of so many new ordinal names. However, it will be well to wait until we have had time to make ourselves thoroughly acquainted with the details of this work, before criticising that which is the result of years of patient labour. We are certainly under deep obligation to the author for his careful and systematic marshalling of the multitude of facts with which he has had to deal; and congratulate him, as well as the directors of the two Surveys, on the successful completion of this first half of the work, which will be a lasting testimony to the zeal and devotion of all who have shared in the labour of its production, and an enduring monument to its author's scientific skill and untiring energy.

E. T. NEWTON

THE DEPTHS OF ALPINE LAKES

La Faune profonde des Lacs suisses. Par le Dr. F. A. Forel, de Morges, Professeur à l'Académie de Lausanne. (Bâle, Genève et Lyon: chez H. Georg, 1885.)

PROFESSOR FOREL, of Morges, already so well known by his numerous pamphlets and short notices on various points in the natural history and the physical geography of the great lake beside which he lives, has in the present work given us the results of the labours of many years, casting into one mass the many fragments and gathering together and correcting where needful the many interesting papers which alone he has hitherto published.

It is a small quarto volume of over 200 pages, with a table of contents and a long bibliographical list appended; it is a pity that there is no index, and the value of the work would have been greatly enhanced had it been illustrated with figures of the new or rare species, and especially with a map of the basin of one at least of the Alpine lakes. Though it professedly deals with the deep-water fauna of the Swiss lakes as a whole, and though frequent allusions and references are made to work done by Prof. Forel and others in a very large number of these and of other lakes, this memoir, as is natural, deals most fully with the fauna of one lake only—the Léman. Of the only other great lake on the northern slope of the Alps—the Bodensee—and of the great lakes of the southern slope—Verbano, Lario, and Benaco—we are told but little. This is, however, a matter of the less importance as the physical surroundings which have affected the fauna of the Léman are almost exactly repeated in the other lakes, and the little that is known of their deep-water life is very similar to what we know of that of the Léman. Of this—his own lake—Prof. Forel has given us a study which may be called complete.

The chief agents affecting the life of the lake are temperature and light: of less importance are the shape and capacity of its basin, the matters dissolved in or held in suspension by its waters, the movements—for the most part superficial—to which its waters are subject. And light is a far more important factor than temperature,—it is at a depth of 30 metres, at the depth that is to say at which chlorophyll-forming vegetation ceases that Prof. Forel draws the line separating the littoral and deep regions of the lake: the actinic action of light ceases at 50 metres in summer, at 100 metres only in winter, owing to the greater transparency of the waters at that season.

Speaking of the conditions of this deep region Prof. Forel says: "They all tend to calm, to rest, to absence of movement. Uniformity, monotony, equality, no motion, no variation, such are the general characters of this region, with which we can compare no other region but that of the deep sea." It is after having studied the flora and fauna of this region almost uninterruptedly for six years that he now gives us what he modestly calls a sketch of the results at which he has arrived.

But in order to be able properly to understand the deep-water life of the lake we must first be properly acquainted with the inhabitants of the upper waters, whether of the shore or of the open. To this end, the first half of the book is occupied with a careful account of the littoral and pelagic flora and fauna. The most interesting point in this section is the statement that the same species of pelagic Entomostraca are common not only to the Alpine lakes but to those also of Scandinavia and the Caucasus. They exist in enormous numbers, thousands of individuals may be captured in one sweep of the net, and they form a very important part of the food of fishes, giving to them, it appears, their characteristic fishy smell; but the species are few. The very wide distribution of these few species is probably brought about by migratory water-fowl.

The deep-water flora of the Léman finds its lowest limit at a depth of 100 metres, and consists entirely of Algæ, chiefly Palmellaceæ and Diatomaceæ, of which the latter are the most abundant in species, but the Palmellaceæ are the most important, forming in many places a felted carpet on the surface of the ooze, and thus giving a more solid bottom, on which animals may move or in which they may live.

The population is much denser in the upper part of the deep region than in the lower part, but even in the deepest part life is present; in the upper part hundreds of animals, dead or alive, may often be obtained at one haul. About 100 species (22 of which are new) constitute this fauna:—Fishes, 14; Insects, 3; Arachnida, 9; Crustacea, 16; Hydroidea, 1; Rhizopoda, 13; Cilioflagellatæ, 1; Gasteropoda, 4; Lamellibranchiata, 2; Annelida, 4; Nematoidea, 3; Cestoidea, 1; Turbellariæ, 18; Bryozoa, 1; Rotifera, 2.

The greater part of these species are evidently the descendants of the inhabitants of the shallow waters, and differ from them chiefly in being smaller and less brightly coloured; the eyes are wanting in *Gyrator coccus*, and have a tendency to disappear in other species; the shells of the mollusks are thinner than is usually the case with those of the littoral zone; and *Fredericella Duplessis*, which is the representative of *F. sultana*, has so far varied from the littoral form that it is never found attached to solid bodies, such as pebbles or fragments of coke, but invariably plunged in the soft ooze after the fashion of a Pennatula.

But of two species of Crustaceans—*Niphargus puteanus* var. *Forelii*, an Amphipod, and *Asellus Forelii*, an Isopod closely related to *A. cavaticus*—Prof. Forel maintains that they are descended, not directly from the allied species of the littoral zone, but from the species *N. puteanus* and *A. cavaticus* which inhabit the subterranean waters, and are commonly found in the wells of nearly the whole of Europe. There is no doubt that *A. Forelii* is closely related to *Asellus aquaticus*, nor that *Niphargus puteanus* is equally closely related to *Gammarus pulex;* the question is merely whether the forms at present inhabiting the abysses of the Léman and other lakes are like *Fredericella Duplessis* directly descended, or indirectly descended, from the littoral forms. It was to the first of these views that Prof. Forel formerly inclined: he now gives his support to the second. And mainly for the following reasons. The modifications which *Niphargus puteanus* and *N. Forelii* have undergone are in all important respects the same; they differ at present only in such unimportant points as the number and length of hairs, setæ, and spines. It is unlikely that precisely the same changes would occur under such very different surroundings as those presented by subterranean waters and the deep waters of a lake. Again, *N. Forelii* is not confined to the Léman, and it is improbable that exactly the same variations should have arisen in different localities. And thirdly, since maintaining a lacustrine origin for *N. Forelii* would compel us to admit that it had varied so far from *Gammarus pulex* since the Glacial period, we can by supposing it to have a subterranean origin allow it a far longer time in which to have undergone modification.

"It is more simple, it is more in conformity with facts to admit that the *N. Forelii* of our lake-bottoms is descended from the *N. puteanus* of the underground waters. That is the conclusion to which I adhere. And I extend this same conclusion to *Asellus Forelii*, and seek its origin also in the *A. cavaticus* of the underground waters."

An interesting illustration of the manner in which animals can adapt themselves to their surroundings is to be found in the species of Limnea and in the larvæ of Diptera (Chironomis) which abound in the Léman. In the littoral zone the Limneas, having a pulmonary sac, are air-breathers; in the deep water, without any change of structure, their breathing is aquatic—their pulmonary sac is filled with water. The case of the Dipterous larvæ is more remarkable. We are told that they swarm in the deep water, and that their respiratory apparatus, consisting of tracheæ, is, like the sac of the Limneas, filled with water instead of air. Larvæ abound, but pupæ are very rare, if not altogether absent, and perfect insects are never seen rising from the surface of the deeper parts of the lake; moreover larvæ of all sizes and ages are found on the bottom at the same season. It would appear from the observations of O. Grimm (*Mém. Acad. imp. St. Pet.*, xv. No. 8, 1870), of St. Petersburg, that these larvæ never attain the perfect stage, but are capable of reproduction by *pædogenesis*.

I have no more space; I can only allude to the discovery of two species of Acanthopus, whose nearest relatives are marine Cythæridеæ; to *Plagiostoma Lemani*, also with marine relations; to the remarkable absence in the deep water of Anodon and of Spongilla, both of them so common in the shallows. Let me conclude in Dr. Forel's words:—

"Others may perhaps regret the absence of the strange things which they had expected to meet with in these strange regions. For my part I have had the intense happiness of being the first to penetrate them, I have endeavoured to explain to myself one by one the mysteries which unfolded themselves to my gaze, and I admire and enjoy their harmony and their simplicity above all. Nature is beautiful and great because she is harmonious everywhere and in everything."

G. H. WOLLASTON

THE CRETACEOUS AND TERTIARY FLORAS OF THE UNITED STATES

The Cretaceous and Tertiary Floras of the United States. By Leo Lesquereux. (U.S. Survey of the Territories under F. V. Hayden, Vol. VII.)

AFTER an interval of nearly ten years, Dr. Hayden presents us with further contributions, by Lesquereux, to the Cretaceous and Tertiary floras of the United States. Those principally illustrated are from the Dakota, Laramie, and Green River groups. The author frankly admits at the outset, p. 4, that "the determinations of the plants are still, and must be for a long time to come, unreliable to a certain degree." This admission must be kept in mind in pronouncing on the merits of the book.

The Dakota beds rest on Permian, and contain a Cretaceous fauna associated with a very rich dicotyledonous flora. No one now doubts their Cretaceous age, although they cannot be correlated exactly, bearing in mind the flora, with anything in Europe. It appears from the revision these fossil plants have undergone, that they are much less closely related to existing genera than was previously supposed. Under such circumstances it seems a pity that less compromising generic names were not substituted for those, such as Sassafras, Acer, Quercus, Hedera, &c., as done in the case of Populites. The known flora of Dakota now consists of 5 ferns, 6 Cycads, a dozen Coniferæ, most of them very unsatisfactory, and no less than 162 Dicotyledons, chiefly remarkable for the large number of handsome palmate leaves among them. One of the most interesting genera, because determined from fruits as well as leaves, is Platanus, a genus also common to our own Lower Eocene of Reading, and thus of a high antiquity. Magnolia is another genus adequately determined, but the remainder rest mainly, if not entirely, on the characters furnished by detached leaves. The vexed question of the age of the Laramie or Great Lignitic series of America is again discussed, and a table given of all its species compared with those of Europe, especially the Eocene of Sézanne in the Paris Basin. As a result the author still holds to the opinion that the formation is an Eocene one. A larger part of the work is occupied with descriptions of the Green River plants, chiefly from Florissant, an incredibly rich locality. This is prefaced by a lucid description of the beds, which exceed 300 feet in thickness, by Mr. S. Scudder. They are principally volcanic ash accumulated in one or more old lake-basins. These and most of the other fossiliferous rocks are situated towards the top of the Green River group, which is reckoned to be 2000 feet thick. The flora contains 228 species, of which 152 are from Florissant, and is referred by Lesquereux to the Oligocene. It was originally thought by him to be Miocene, but the detailed comparisons he has made between it and that described by Saporta from Aix, in Provence, prove that he is justified in putting its age further back. Indeed it bears a marvellous resemblance to that of Bournemouth, and had he been able to make comparisons he would perhaps have assigned it a still earlier date. It is a matter of the greatest interest to find in America a flora corresponding to those of Aix and Bournemouth, and not represented anywhere to the north. The last pages are occupied with descriptions of some new Miocene plants from various localities. The book is illustrated by fifty-nine coloured plates, and however we may differ as to the value of the determinations themselves, all will agree as to the great service rendered to science by the publication of such an important mass of data for future comparison. J. STARKIE GARDNER

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Coal-Dust Question

ON several occasions during the last five years, Sir Frederick Abel has referred to the history of the coal-dust question, and to my connection therewith; and as his views on this subject do not altogether correspond with mine, I desire, with your permission, to state in this place how much, and in what particulars, I differ from him.

In his address to the Society of Arts, delivered on the 17th of November last, Sir Frederick says: "Several well-known French mining engineers published, many years after Faraday and Lyell wrote, observations and experimental results as new, which were simply confirmatory of those philosophers' original statements and conclusions, and to some extent this was also the case in still more recent publications in this country by Galloway and Freire-Marreco."

Faraday and Lyell's statements and conclusions were to the following effect:—

1. Fire-damp is not the only fuel in an explosion.

2. The coal-dust is swept up by the blast and is partially burnt.

3. (Speaking of Haswell Colliery explosion)[1] "There is every reason to believe that much coal-gas was made from this dust in the very air itself of the mine, *by the flame of the fire-damp*, which raised and swept it along, and much of the carbon of this dust remained unburnt only for want of air."

That is to say, the flame of the fire-damp is extended, and the effect of the explosion is aggravated by the presence of the coal-dust.

[1] *Phil. Mag.*, 1845.

The Committee of the Coal Trade, who replied to Faraday and Lyell's report in a letter dated February 7, 1845, do not appear to have thought those authors' remarks about coal-dust of sufficient importance to be noticed at all. Nor do the authors themselves seem to have attached any particular importance to them save as a record of a curious physical and chemical fact; for after making them they immediately turned, like all their predecessors and most of their successors, to the contemplation of imaginary magazines of fire-damp as a means of accounting for the explosion. Moreover, both of them lived for many years afterwards, during which one great explosion occurred after another, and yet we do not find that either of them ever lifted so much as the tip of his little finger to point to coal-dust as the probable cause of the catastrophes.

In 1855, M. du Souich, Ingénieur des Mines, said,[1] "A sort of crust of light coke, which could be gathered from the timber at various points, could only have originated from the coal-dust swept up in the working places and carried to a distance by the extremely violent air-current caused by the explosion. This dust being itself partially inflamed *could continue the effects of the fire-damp by carrying them further*" (*peut continuer les effets du grisou en les portant plus loin*).

In 1861,[2] M. du Souich and M. Estaunié again insisted on the same thing in similar terms.

In 1867,[3] M. du Souich again developed the same opinions.

In 1864,[4] Verpilleux de Reydellet, A. Burat, Poumairac Baretta and other engineers emitted opinions similar to the foregoing.

In 1875,[5] M. Vital wrote, "Extremely fine coal-dust is a cause of danger in dry working places in which shot-firing is carried on; in well-ventilated workings it may of itself alone give rise to accidents; in fiery workings it increases the chances of an explosion, and when an accident does occur *it aggravates the consequences of the fire-damp flame*" (*coup de feu*).

In 1875,[6] MM. Desbief and Chansselle gave a short historical *résumé* similar to that of M. Haton, and quoted an opinion of M. Verpilleux which appears to resemble my own, but has never, so far as I am aware, been put prominently forward by the author nor supported by experimental or other proof, namely: "M. Verpilleux, who attaches great importance (*importance capitale*) to coal-dust, was one of the first to call attention to it; comparing a fire-damp explosion to the detonation of a gun, he went so far as to say that the dust represents the powder and the firedamp the priming."

In March, 1875, Sir Frederick, then Professor, Abel, addressing an audience at the Royal Institution on the subject of "Accidental Explosions," referred to explosions in mines, and mentioned the researches that had been made by Mr. R. H. Scott and myself up to that date. He also speaks of dust explosions in flour mills, &c.; but, as showing the small importance he attached to anything that had been previously said or done in regard to coal-dust, it is remarkable that he does not even refer to its existence.

I had been investigating the subject of great colliery explosions since the year 1870, but had been unable to discover any explanation of their occurrence wholly satisfactory to myself. At the commencement of my work I had read all, or nearly all, the English literature connected with it then extant, and amongst other things the report and article of Faraday and Lyell on the Haswell Colliery explosion, and the reply of the Committee of the Coal Trade;[7] but, so little impression did Faraday and Lyell's remarks about coal-dust make upon me at the time, that I afterwards forgot I had read them, and was only reminded of the fact by seeing it recorded in an old note-book of my own some time after the publication of my first paper. I retained the impression, however, for in the paper[8] referred to I wrote: "The accounts of colliery explosions published in this country hardly ever allude to the existence of coal-dust; and when they do so, in one or two cases [it should have been one case only] it is for the purpose of suggesting that the gases disengaged from it by the heat of the fire-damp flame would no doubt be ignited and tend to increase the force of the explosion."

It did not for a moment occur to me that this, which is Faraday and Lyell's view, could ever be accepted as an explanation of the phenomenon I was trying to elucidate.

[1] "Rapport de M. Haton de la Goupillière: Des Moyens propres à prévenir les Explosions du Grisou," 1880.

[6] *Comptes rendus des Réunions mensuelles de Saint Etienne*, June, 1875.
[7] *Iron*, June 1, 1878. [8] *Proc. Roy. Soc.*, 1876.

In the beginning of the year 1875 I removed to South Wales, and soon discovered that all the collieries in which great explosions had occurred were dry and dusty. My previous experience was almost wholly confined to damp mines, in all of which, with one exception (Nitshill), there was no coal-dust, and in none of which, with the same exception, a great explosion had ever occurred. The impression referred to above probably exercised a certain influence at that time in helping me to form the conception of what I believe to be the true explanation of great colliery explosions. In the words of my first paper[1] it is as follows: "If it could be shown that a mixture of air and coal-dust is inflammable at ordinary pressure and temperature, there would be no difficulty in accounting for the extent and violence of many explosions which have occurred in mines in which no large accumulations of fire-damp were known to exist; for it is only necessary to suppose that a violent gust of wind (originated, for example, by the explosion of a small accumulation of fire-damp) had swept through the adjoining galleries, raising a cloud of dust into the air, and then all the other phenomena would follow in regular order. The flame of the originally inflammable mixture would pass into the newly-formed one, expanding its volume; the disturbance would be propagated over an ever-widening area, until that area might possibly become co-extensive with the workings themselves; and *the consequences would be the same as if the whole space had been filled with an inflammable mixture before the disturbance began.*"

I demonstrated by an experiment first made on the 3rd of July, 1875, that air containing less fire-damp than can be detected by the ordinary means of testing the air in mines, is rendered inflammable at ordinary pressure and temperature when fine dry coal-dust is added to it. This was the first step towards proving the truth of my theory.

In the same paper I also stated, "It is always possible that if coal-dust could be made fine enough and were thoroughly mixed with dry air in the proportion of about 1 pound to 160 cubic feet of air, the mixture might be inflammable at ordinary temperature, or, *if not*, it might at least be so nearly inflammable that an explosion begun in it, in a confined space, might be propagated through it."

In my second (1879) and subsequent papers to the Royal Society, I stated the further opinion, first, as the result of more elaborate experiments, and secondly, as the result of a careful personal investigation and consideration of all the circumstances attending the occurrence of several great explosions, that, "A fire-damp explosion occurring in a dry coal-mine is liable to be indefinitely extended by the mixture of air and coal-dust produced by the disturbance which it initiates." This was the final step.

Of this, Sir Frederick says:[2] "Mr. Galloway was certainly the first to enunciate the conclusion that a small proportion of fire-damp is essential to impart to a mixture of air and coal-dust the power of propagating flame, though *he afterwards abandoned this conclusion in favour of the one some time previously accepted by Marreco*, to the effect that fire-damp is altogether unnecessary for the conveyance of flame with explosive effect by a mixture of dry coal-dust and air."

In January, 1878, I commenced a series of articles in *Iron* on coal-dust explosions, hoping thereby to arouse an interest in the subject, and, amongst other items of information, I gave translations of Vital's and Desbief and Chanselle's papers. Seven of these articles had already appeared when, in April, 1878, Prof. Marreco (to whom I had myself sent copies of them) and Mr. Morison, read their first paper before the Chesterfield Institute. They say, "Before the writers had the opportunity of learning what had already been accomplished abroad, their attention was directed to the subject by a paper read by Mr. W. Galloway before the Royal Society, in which he related his experiment in producing explosion in a mixture of fire-damp and air impregnated with dust. The opinion expressed in that paper, viz., that coal-dust was explosive only in an atmosphere containing a minute proportion of fire-damp, induced the writers to still further extend the scope of the experiments, and endeavour to discover whether coal-dust could by any means be exploded in an atmosphere totally free from fire-damp."

The arrangement to carry out the experiments here spoken of was made between Marreco and myself in the end of 1875 or beginning of 1876, and was referred to in my first paper (1876) thus: "It would be premature to draw any positive inference from my experiments with gunpowder shots, as they are by no means so satisfactory as I could wish, and I am glad to be able to state that Prof. Marreco, of Newcastle-on-Tyne, intends to investigate this question with more substantial apparatus."

Returning to Sir Frederick's remark, I would say that I abandoned no previous conclusion "in favour of one some time previously accepted by Marreco." I then held, and still hold, what is now a universally accepted opinion amongst mining men, that a mixture of air and fire-damp, which is not inflammable at ordinary pressure and temperature, may be rendered inflammable by the addition of dry coal-dust, and I was prepared, as soon as proof satisfactory to myself was forthcoming, to extend the area of my opinion, so as to include a mixture of fine dry coal-dust and air in the same category. This latter proof alone was necessary to the firm establishment of the theory enunciated at the commencement of my first paper, and for that reason Sir Frederick's statement appears to me to be wanting in logical sequence.

Neither the statement made by Marreco and Morison, that they intended to "endeavour to discover whether coal-dust could by any means be exploded in an atmosphere totally free from fire-damp," nor the results of the experiments published by them, appear to me to warrant Sir Frederick in taking up this position; for, concerning these very experiments of Prof. Marreco's he had himself remarked in the year 1880:[1] "It does *not appear that* in the numerous experiments made at Harton Colliery by the exposure of naked flames in currents of air laden with coal-dust, and by firing small cannon (representing blown-out shots) placed in various positions in such air-currents, *any indication has been obtained of a propagation of flame by the coal-dust.*" How then could Marreco have concluded that "fire-damp is altogether unnecessary for the conveyance of flame with explosive effect in a mixture of coal-dust and air"?

Sir Frederick continues to say, regarding myself: "Even his latest publication on the subject tends in the same direction, and emphasises his desire to 'claim that no earlier author had gone the length of crediting coal-dust with the *rôle* of principal agent, and relegating fire-damp to a secondary position.' The more recent results of other writers in this direction have, however, conclusively demonstrated that this is far too great a length to go, and that while on the one hand a very fine dry and highly inflammable coal-dust may, when raised and mixed with air by the force of a blown-out shot, become inflamed, and may then carry flame to considerable distances with a rapidity and violence of action similar to that of a fire-damp explosion, the extent to which, on the other hand, flame is propagated under corresponding conditions by most descriptions of coal-dust in the complete absence of fire-damp is very limited."

Sir Frederick and those whose opinions he here quotes appear to have omitted to take one element into consideration which has an important bearing upon the case. To this I may have occasion to refer more particularly at an early date.

W. GALLOWAY

Sunset-Glows

I WISH to call the attention of observers to a peculiar phenomenon which has been frequently noticed by me lately in connection with these sky-scenes. A very bright after-glow was visible here on October 27 last. I believe the date is correct, although I have unfortunately mislaid my day-book; the facts, however, I can vouch for otherwise, as they were detailed at the time. At 5 p.m. a heavy bank of cumulus was to be seen extending along the south-western sky-line, about 5° above and closely parallel to the horizon. High over this bluish bank of cloud rose the yellow haze of departing sunlight. This diffused after-glow was plainly intersected by numerous (I counted twenty-two) delicate streaks of nebulous stratus. These intersecting lines (they were scarcely "bands") were horizontal and parallel, piled up, as it were, above one another as high as 25° from the sea-line. The lowest hung apparently about half a degree above the gilded upper edge of the dark cumulus. On November 4, just before sunset, I exposed a gelatine plate, and succeeded in obtaining a photograph, in which seven of these narrow horizontal cloud-streaks can be faintly seen. On December 1 the following note was made:—4.20 p.m. Wind light,

[1] *Proc. Roy. Soc.*, 1876.
[2] *Journal Soc. Arts* No. 20, 1885, p. 23.

[1] "Report on the Results of Experiments made with Samples of Dust collected at Seaham Colliery, &c.," 1880.

N.N.W. Sunset-glow intersected by five horizontal dark cloud-streaks in the west. On the 2nd inst., at 4.20 p.m., five cumulo-strati were visible in the west, separated by parallel and horizontal orange-coloured bands. Above these were numerous (probably twenty) delicate dark lines traversing—also horizontally—the upper roseate after-glow. On the 10th and 11th inst., somewhat similar phenomena were visible here. On the 15th inst., with a light southerly air, eleven cloud-bands were seen by me at 4.30 p.m. In this case only, they were not parallel to the sea-line, but followed the direction of the west-north-west horizon. I have seen the same appearances once or twice since the last date. The above phenomena are new to me, and I have not met with any detailed account of them elsewhere. I have therefore ventured to address you on the subject. Can these cloud-streaks represent stratified air-dust in the upper regions of our atmosphere? W. AINSLIE HOLLIS

Hove, Brighton, December 26

Iridescent Clouds

THERE was a very striking display of iridescent clouds this afternoon. I noticed it first at about 3.40 p.m. The prismatic colours were pretty strongly marked, and the intense pearly brilliance of the delicate cirri was most striking. It is still visible (4.40 p.m.), though, of course, its lustre is much diminished. A gale is blowing from the west, and there has been an orange after-glow. Similar phenomena were described in your columns about this time last year. They were well seen in this part of the country. EDWARD GREENHOW

Earsdon, Newcastle-on-Tyne, December 28

YESTERDAY, clouds very similar to those seen a year ago made their appearance, and there were a few of them again this morning. I first noticed them at 11.30 a.m., and they were extremely magnificent after sunset, showing three or four spectra of colour, and they were especially striking about 4.10 p.m., when they appeared very bright against the purple glow of the sky. Their chief difference from the clouds last December was that they were not bounded by straight lines, and that there was no special amount of blue in the colouring, as was usually the case a year ago. The chief colours were pink and green.

Sunderland, December 29 T. W. BACKHOUSE

Ventilation

IN reply to the query of J. F. Tennant, there can be no doubt that the cause of the failure of the ceiling ventilators is a deficiency of fresh-air supply to the room. An ordinary chimney with a fire will, if unchecked, draw an amount of cold air into the room which would make the temperature about the same as that of the outside air, and without enormous volumes of warmed air it is, I think, impossible to expect any service whatever from the system of ventilation from ceiling-flues, as recommended by the writer of the article referred to. Since writing my first letter I have seen a regenerator lamp attached to one of these ceiling-flues, and the down-draught was so strong and persistent as to reverse the natural current of the lamp, rendering its use impossible. The air-inlet to my own rooms consists of a channel in the wall of every room opening into ten one-inch holes at the fireplace, but this, of course, is utterly inadequate to supply one-tenth of the air required by the flue, and the ventilator and the ventilating-shaft supplement this supply by working the wrong way. THOS. FLETCHER

Warrington

A VERY common source of trouble with respect to ventilation is the absence of any arrangement for the supply of air to fires. So long as a fire draws on the general atmosphere of the room it is supposed to warm for its supply of oxygen, there must be the "draughts" so often complained of, and people are warm on the side next the fire, and cold on the other. I should suppose this is what happens in Mr. Fletcher's case, described in his letter in NATURE (pp. 153-4). If so, there is simply a sort of "tug-of-war" between the longer chimney-flue and the shorter ventilation flue, with the additional advantage on the side of the former that the column of air ascending the chimney is necessarily much warmer than that which should ascend the ventilation flue. If, however, Mr. Fletcher will have a couple of holes bored in his floor, one on each side of the fireplace, so as to supply air directly to the fire, the "pull" of the fire on the air of the room will cease, the room will be warmer, and his ventilation flue should work satisfactorily. I warm thoroughly a room with considerably over 2000 square feet of floor area by means of three small stoves. When first used the stoves were inefficient, as there was a draught all round each towards it. A common rain-water pipe "bend," inserted in the floor immediately in front of the aperture of each stove for admitting the air-supply, stopped the draughts, and at least doubled the efficiency of the stoves as warmers. With the help of Tobin tubes there is now a gentle current of warmer air *from* each stove. The heated and vitiated air escapes through ventilators fixed in the ridge of the roof. W. WILKINSON

Eldon, Bishop Auckland, December 23

Friction and Molecular Structure

IN your number of December 17 (p. 154) is a letter signed by Mr. E. Geoghegan, referring to the effect of moderate friction on the molecular structure of glass lamp-chimneys. This I have very frequently observed, and it would be very interesting to have suggestions as to its cause and means of prevention. I often read under one of Sugg's Argand gas-burners, the chimney of which almost invariably breaks on first heating after cleaning. First of all, washing was tried, to remove the mottled milky stain which forms on the glass, and then rubbing with a silk cloth or cotton rubber, but there does not seem to be much difference in the result, as the glasses, the best I can obtain, generally break. C. K. BUSHE

Bramhope, Old Charlton, Kent, December 25

The Longevity of Insects

WITH reference to the longevity of insects, it is worth while to record that we kept a ladybird from the September of one year to the September of the following. She was a handsome specimen of the seven-spotted ladybird, and her eggs, which were laid in the winter, after passing through the miniature crocodile stage, produced perfect insects in February. It is curious to watch the imago emerging from its dusky case; at first no spots are visible on its buttercup-yellow "shards," which contrast strongly with the jet-black legs and underneath; but in a very few hours the first brilliancy has gone, the spots appear faintly, and in a few days the final red with the black spots is established. E.

December 28

SOUTH AMERICAN BIRD-MUSIC

MR. BURROUGHS, an American naturalist, in his "Impressions of some British Song Birds," has said:—"Many of the American songsters are shy wood-birds, seldom seen or heard near the habitations of men, while nearly all the British birds are semi-domesticated, and sing in the garden and orchard. This fact, I had said, in connection with their more soft and plaintive voices, made our song-birds seem less to a foreign traveller than his own." These words apply with much greater force to the birds of South America, the species being much more numerous and less well known than in the northern portion of the continent; while the true songsters are relatively fewer, owing to the presence of several large songless families, such as the tyrants, humming-birds, and others.

The South American songsters certainly do not, like those of Europe, mass themselves about the habitations of men, to sing there as if sweet voices were given to them solely for the delectation of human listeners; they are pre-eminently birds of the wild forest, the marsh, and the savannah; and the ornithologist or collector from Europe, whose principal object is to make a large collection, has little time to make himself acquainted with the accomplishments of the species he desires above all things to shoot. Nor is this all. Doubtless there remains in the minds of most people something of that ancient notion that brilliant-plumaged birds utter only harsh, disagreeable sounds; while the sober-toned songsters of temperate regions—especially those of Europe—have the gift of melody; that sweet songs are heard in England, and screams and grating notes within the tropics. Only we know now that the obscure species there are greatly in excess of the brilliant ones. It is quite possible, however, that the tropics, so rich in other respects, though by no means the realms "where birds forget to sing," do not excel, or even equal, the temperate regions in the amount and quality of their bird melody. Mr. im Thurn only echoes the words of many English travellers in the tropics, when he says, in his recent work on British Guiana:—"The almost entire absence of sweet bird-notes at once strikes the traveller who comes from thrush and warbler-haunted temperate lands." Mr. Bates, on this subject, says:—"The few sounds of birds are of that pensive and mysterious character which intensifies the feeling of solitude rather than imparts a sense of life and cheerfulness."

On the question of tropical bird-music much remains to be said by future travellers; but South America is not all tropical, and travellers visiting the southern temperate portion of that continent might have looked to find there melodists equal to those of Europe and North America; for even assuming that to utter agreeable sounds a bird, wherever found, must be fashioned after the pattern of some European form, we find that the typical songsters of the north—the thrushes, wrens, warblers, finches, &c.—are well represented in the Plata, Chilian, and Patagonian regions. As a fact, the best songsters there belong to the wide-ranging American genus *Mimus*, while in the more tropical Icterine family there is great variety of language, and some exceedingly sweet voices.

Of the great naturalists of recent times who have depreciated South American bird-music, I will mention Darwin only, as very great importance must always be attached to his words, even when he fails to show his usual discrimination. He says of the common *Mimus calandria*:—"It is remarkable from possessing a song far superior to that of any other bird in the country; indeed, it is nearly the only bird in South America which I have observed to take its stand for the purpose of singing." He then adds that the song is like that of the sedge warbler.

There are many better singers than the *M. calandria*; and as to its being nearly the only bird that takes its stand for the purpose of singing, there are, in the Plata district alone, a greater number of birds with that habit than in England; though, taking the number of species in the two countries, the Plata singers are relatively fewer. It is equally beside the mark to compare the sedge warbler with the Calandria, the performance of the former bird resembling that of the other only as a slight sketch may be said to resemble a finished painting.

Darwin does not say much about the singing of birds, and appears to have taken but little interest in the subject, possibly because this species of natural melody gave him little or no pleasure; otherwise he could scarcely have written of the Diuca Finch that "the male during incubation has two or three pleasant notes, which Molina, in an exaggerated description, has called a fine song." The fact is, the old Chilian naturalist scarcely does justice to the song of the Diuca, which is mellower in sound than any other finch-melody I am acquainted with. Of his account of the singing of the Thenca mocking-bird, the Thili, the black-headed finch, Loyca, and various other species, Darwin says nothing.

Not all the European writers whose words carry weight, however, have turned a deaf, or, at any rate, a very unappreciative ear to the bird-music of the great bird-continent. Azara is a notable exception. He was not a mere collector, nor was he even a naturalist in the strictest sense of the word; but, made fit for his task by a keen faculty of observation, and an insatiable craving for knowledge of all kinds, he went into the forest to watch the birds and write the history of their lives. In Spain he had been familiar from childhood with the best songsters of Europe, and in Paraguay he paid great attention to the language of the species he noticed. He makes mistakes sometimes, when speaking of the nesting or other habits, but when describing their songs, he records his own impressions only. With the works of his contemporary, Buffon, he only became acquainted after having completed his own observations; and the voluminous strictures on the French naturalist, which burden, and to some extent spoil, the otherwise delightful "Apuntamientos," were only inserted after his own descriptions had been written.

In his introductory pages, entitled "De los Paxaros en General," he refers to Buffon's well-known opinion concerning the inferiority of American songsters, and says:—"But if a choir of singers were selected in the Old World, and compared with one of an equal number gathered in Paraguay, I am not sure which would win the victory." In another place, in allusion to the same subject, he says:—"They are mistaken who think there are not as many and as good singers here as in Europe."

To return for a moment to Mr. Bates's words, already quoted, bird-music of that "pensive and mysterious" character he mentions is to many minds more pleasing than the loud, cheerful, persistent singing of many highly-esteemed British singers, like the chaffinch and song-thrush.

Mr. Bates also heard in the Amazonian forest, "another bird that had a most sweet and melancholy song, uttered in a plaintive key, commencing high, and descending by harmonic intervals."

Of the common house-wren of the Plata, Azara says that its song is "in style comparable to that of the nightingale, though its phrases are not so delicate and expressive; nevertheless, I count it amongst the first songsters." He speaks even more highly of the voice of the Todo Voz (*Cistothorus platensis*), which greatly delighted him with its sweet, varied, and expressive melody. The members of this melodious genus, and of the allied genera, are found throughout South America, from Panama to Patagonia, and we know from others besides Azara that their music does not dissolve away in the tropics, or turn to harsh sounds. Mr. Wallace heard a Cistothorus singing very sweetly on the shores of the Amazon, and D'Orbigny, in the "Voyage dans l'Amérique Méridionale," thus describes the singing of the *Thryothorus modulator*, which he heard in Yungas, in Bolivia:—"Perched on a bough overhanging the torrent, its rich melodious voice seemed in strange contrast to the melancholy aspect of its surroundings. Its voice, which is not comparable with anything we have in Europe, exceeds that of the nightingale in volume and expression, if not in flexibility. Frequently it sounds like a melody rendered by a flute at a great distance; at other times its sweet and varied cadences are mingled with clear piercing tones or deep throat-notes,—in one word, a grave music composed of the purest sounds. We have really no words adequate to express the effect of this song, heard in the midst of a nature so redundant, and of mountain scenery so wild and savage."

It might be thought that in this description allowance must be made for the enthusiasm natural to a Frenchman, but Mr. Bates, certainly the most sober-minded naturalist that ever penetrated the Brazilian forests, gives a scarcely less fascinating account of a melodist closely allied to D'Orbigny's bird, if not identical with it. "I frequently heard," he says, "in the neighbourhood of these huts the realejo or organ-bird (*Cyphorhinus* *cantans*), the most remarkable songster by far of the Amazonian forest. When its singular notes strike the ear for the first time the impression cannot be resisted that they are produced by a human voice. Some musical boy must be gathering fruits in the thickets, and is singing a few notes to cheer himself. The tones become more fluty and plaintive; they are now those of a flageolet, and, notwithstanding the utter impossibility of the thing, one is for the moment convinced that some one is playing that instrument. . . . It is the only songster which makes an impression on the natives, who sometimes rest their paddles whilst travelling in their small canoes, along the shady by-paths, as if struck by the mysterious sound."

Outside of these pre-eminently tuneful groups—thrushes, warblers, finches, &c.—there are many species belonging to groups considered songless which nevertheless do sing, or have, at any rate, some highly musical notes. Dendrocolaptine birds are not, strictly speaking, songsters; but they are loquacious, and fill the woods with sound, often pleasant and laughter-like in character; and in many species the male and female combine their voices in a pretty kind of chorus. In the well-known oven-bird this is very striking, the male and female singing a ringing joyous duet in different tones, producing an harmonious effect. D'Orbigny notices this harmonious singing of the *Furnarius*. The hirundines in many cases have voices utterly unlike those of Europe, which as a rule only emit a squeaking twitter. They have, on the contrary, rather thick tones, in many cases resembling the throat-notes of the skylark, and some have a very pleasing set song. The human-like tones of some of the pigeons, the plaintive fluting of the Tinamous, even the notes of some kingfishers and cuckoos, contribute not a little to the bird-music of South America. Waterton's words about the "songless" bell-bird are well known, and, allowing that he goes too far when he says that Orpheus himself would drop his lyre to listen to this romantic sound, it is still certain that there are hundreds of species, which, like the bell-bird of the Orinoco forests, utter a few delightful notes, or produce a pleasing effect by joining their voices in a chorus. Thus, Mr. Bates speaks of the *Monasa nigrofrons*—a barbet:—"This flock of Tamburi-para were the reverse of dull: they were gamboling and chasing each other amongst the branches. As they sported about they emitted a few short tuneful notes, which altogether produced a ringing musical chorus that greatly surprised me."

But even leaving out all these irregular melodists; also omitting the tanagers, the tyrants, and their nearest allies; the Dendrocolaptidæ and Formicaridæ, and the humming-birds—these few families I have mentioned comprising about 1800 species—there would still be a far greater number of regular songsters than Europe can show, so great is the bird-wealth of South America; and concerning the merits of their music I can only say that Azara and D'Orbigny did not hear the best singer—the *Mimus triurus*. It would have been strange indeed if in that portion of the globe, so inconceivably rich in species, and where bird-life has had its greatest development, the faculty of melody had not been as highly perfected as in other regions.

A very long time has passed since Azara made that remark about a choir of song-birds selected in Paraguay, and our knowledge on this subject—possibly because it has been thought unimportant—has scarcely been added to since his day; but it seems to me that when the best singers of two regions have been compared, and a verdict arrived at, something more remains to be said. The species which "formally take their stand for the purpose of singing" sometimes delight us less than others which have no set song, but yet utter notes of exquisite purity. Nor is this all. To most minds the dulcet strains of a few favoured songsters contribute only a part, and not always the largest part, of the pleasurable sensations received from the bird-voices of any district. All natural sounds produce, in some measure, agreeable sensations: the pattering of rain on the leaves, the lowing of cattle, the dash of waves on the beach, the "springs and dying gales" of a breeze in the pines; and so, coming to birds, the clear piercing tones of the sandpiper, the cry, etherealised by distance, of a passing migrant, the cawing of rooks on the tree-tops, afford as much pleasure as the whistle of the blackbird. There is a charm in the infinite variety of bird-language heard in a sub-tropical forest, where birds are most abundant, exceeding that of many monotonously melodious voices; the listener would not willingly lose any of the many indescribable sounds emitted by the smaller species, or the screams and human-like calls, or solemn, deep booming or drumming of the larger kinds, or even the piercing shrieks which may be heard miles away. The bird-language of an English wood or orchard, made up in most part of melodious tones, may be compared to a band composed entirely of small wind-instruments with a very limited range of sound, and which produces no storms of noise, eccentric flights, or violent contrasts, or anything to startle the listener—a sweet but somewhat tame performance. The sub-tropical forest is more like an orchestra in which a countless number of varied instruments take part in a performance in which there are many noisy discords, while the tender, spiritual tones heard at intervals seem, by contrast, infinitely sweet and precious.

W. H. HUDSON

FORESTRY

THE report of the proceedings of the Select Committee on Forestry which sat during the past summer does not, perhaps, throw any more light on the condition of forestry in this country than was possessed before the appointment of the Committee, for the substance of the evidence given is for the most part to be found in the various works and reports on forestry that have appeared from time to time during the past few years; nevertheless the evidence of such men so well versed in forest conservancy, especially with regard to India, as Dr. Cleghorn, Col. Michael, Col. Pearson, and Mr. W. G. Pedder is of much value, as it brings together in a collected form information that has hitherto been much scattered.

The subject of forest produce is one that is but little understood or even thought of by people in general. It is supposed by most people to relate only to the supply of timber, which indeed of itself is of very great importance; but when we consider the other products—such as gums, resins, oils, fibres, and such like—the enormous money value becomes more apparent, as well as the great importance of the forests as sources of many absolute necessities of life. The evidence of Col. Michael fully illustrates this and is especially valuable from this point of view. Taking the subject of Indian timbers alone, the value of teak was fully set forth when it was shown to be unequalled for the backing of ironclads and for shipbuilding generally, as offering the greatest resistance of any known woods. Questioned as to whether teak was capable of being brought into this country as a commercial article at a remunerative profit, Col. Michael replied that, judging from the price realised for some logs sold at the Forestry Exhibition at Edinburgh and from other information obtained, no doubt existed that the trade in teak might become a very remunerative one. It was shown further that in 1883 647,000*l*. worth of teak was imported into England; but Col. Michael also touched upon what, if put upon a proper footing, might equally, or perhaps more so, become a source of revenue to India and a boon to this country—namely, the introduction of the more ornamental woods for cabinet purposes. There is, of course, always a steady demand for British-grown timbers such as oak, elm, ash, maple, &c., but these have to be supplemented by foreign woods of a more ornamental character, and of these mahogany, rosewood, ebony, satinwood, and such like are the best known. From amongst Indian timber trees a long list might be made of woods which are now almost unknown out of their native country—such, for instance, as the East Indian cedar (*Cedrela toona*), which is a reddish-coloured wood with a splendid wavy or feathery figure; the tree is also found in Australia, where the wood is highly valued; the padouk (*Pterocarpus indicus*), the deep-red-coloured wood of which attracted so much attention at the Edinburgh Exhibition last year; the Malabar Kino tree (*Pterocarpus marsupium*), also a finely-marked deep-red wood, several species of *Terminalia*, durable woods of a brown colour with darker brown markings. Many others might be mentioned, but the most beautiful of all the Indian woods for its ornamental character is the Chittagong wood (*Chickrassia tabularis*). This is of a brown colour, with transverse lighter silvery-brown wavy markings, which impart to it a varying depth of light and shade, which, when polished, imparts a peculiar and charming lustre. All these woods take a high polish, and would be invaluable for cabinet-work. Fine specimens of these and many others are in the collection of Indian timbers exhibited in the No. 3 Museum at Kew.

On the question as to the durability of the Scotch fir (*Pinus sylvestris*) Col. Pearson gave an opinion which is worth quoting. He says:—"I think myself that as the value of the foreign imported timber increases, as it must do as the quantity diminishes, people will come to appreciate more the Scotch fir, because I know many barns which have been boarded with Scotch fir for twenty years, and which are standing perfectly well: but it is convenient to get the imported boards ready sawn out, and where the people can get them cheap they do not pay attention to the Scotch and home-grown timber. But, speaking for myself, I should say that Scotch fir is a perfectly good wood as long as it is sufficiently mature, and I think, as foreign wood becomes dearer, as it will in a few years, English timber and Scotch timber will become of a value which it has not now."

On the general subject of the proposed Forest School Col. Pearson expressed himself in favour of a Chair of Forestry at the Edinburgh University, but he further stated that he had no actual faith in lectures in the school unless illustrated by practical instruction. "If," he says, "you tell a man in the lecture room that such and such consequences will take place, and do not show him the consequences on the spot, he does not believe anything about it; it goes in at one ear and out at the other; he will think it all nonsense; but if you want to impress your teaching upon him, you must take him out into the forests and show him the operations of Nature." Regarding the extent or scope of the School, Mr. Thiselton Dyer, in reply to Sir Edmund Lechmere whether he would not make the School of Forestry applicable to India and the Colonies as well as to our own country, said, "I should like to get all the fish possible into the net, and if we had such a school, to make it as useful as possible. I think it is surprising, considering how large is the interest of the English race in forestry, that except in India we have taken no kind of active interest in the subject: although we own more forests in the world than any other race, we are at present, except in the most piecemeal fashion, absolutely washing our hands of the whole business." Mr. Dyer, in his evidence, further pointed out by way of illustration a few of what are usually called the minor industries of forest produce, which in the aggregate become of considerable national importance.

It is to be regretted that the Committee was not nominated at an earlier period of the session. The first sitting was on July 14, and at the two subsequent sittings on July 21 and 24, witnesses only were examined. The report of the Committee refers to the impossibility of concluding their investigations during the Session, and "recommends that a Committee on the same subject should be appointed in the next Session of Parliament."

JOHN R. JACKSON

OBSERVATIONS ON THE RECENT CALCAREOUS FORMATIONS OF THE SOLOMON GROUP, MADE DURING 1882-84[1]

ON account of the treacherous character of the natives of the Solomon Group, no extensive geological observations have ever been made in these islands from the period of their discovery by the Spaniards three centuries ago. For this reason my excursions in these regions were not free from personal risk; in many places they were considerably curtailed, and in some islands they had to be abandoned altogether.

This archipelago includes seven or eight large islands, some of which are from seventy to eighty miles in length, and the highest from 8000 to 10,000 feet in height. Besides these, there are a great number of smaller islands and islets, some of volcanic and others of recent calcareous formations. Restricting my remarks to those islands which are wholly or in part composed of these calcareous rocks, I may observe that, although only able to become acquainted with a small portion of the Solomon Group, the islands which I examined represent the different types of islands that there exist.

In this, the largest of the Pacific groups, I not only found existing fringing-reefs, barrier-reefs, and atolls, but I discovered pre-existing reefs of these three chief classes which have been recently elevated to a height often of several hundred feet above the sea. My observations on these recently-elevated reefs and their foundations have enabled me to approach the problem of the formation of coral reefs by the inductive rather than by the *a priori* method: for it is evident that in passing from the consideration of a probable cause of the formation of existing reefs to the examination of ancient reefs that have been raised with their foundations above the sea, we enter a domain of greater certainty. I purpose in this abstract to state concisely the principal characters of the islands which are wholly or in part of calcareous formations; then to draw four limited inferences from these facts of observation without reference to any particular views that may be held on the subject of the origin of coral reefs; and finally to compare such conclusions with the prevailing views on that subject.

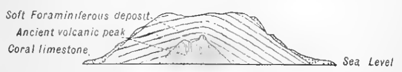
In the first place there are numerous small islands and islets less than a hundred feet in height, which are composed in mass of coral limestone. Of this class Stirling Island may be taken as an example. In the bold cliffs, which form the weather coast of this small island, there are numerous imbedded masses of the reef-building corals, many of them measuring four feet across, the majority of them in the position of growth, but some of them inverted.

The island of Ugi, which is six miles in length and about 500 feet in height, may be taken as a type of the next class. Its geological structure may be briefly described as composed in bulk of a soft earthy bedded deposit, possessing the characters of the "volcanic muds" of the *Challenger* soundings, containing numerous Foraminifera, and encrusted near the coast by coral limestone, which almost disappears in the higher regions. The greatest thickness of the coral limestone that I found in this island was between 90 and 100 feet. As one ascends the higher slopes of the island the coral limestone thins away, and

[1] By H. B. Guppy, M.B., F.G.S., late Surgeon of H.M.S. *Lark*. [Abstract of a paper read before the Royal Society of Edinburgh, on June 15th, 1885, being communicated by Mr. John Murray.]

only occasional fragments occur in the red argillaceous soil. The greatest elevation at which I found the coral rock was about 425 feet above the sea. The soft Foraminiferous deposit, which forms the mass of the island, is regularly bedded, the dip varying usually between 10° and 15°, but it may rise to as much as 35°. Entire shells are rarely found in these beds, the Foraminiferous tests being usually the only organic remains visible to the naked eye.

The island of Treasury affords an example of the next type of island. It is oval in shape, has a length of nine miles, and rises about 1150 feet above the sea. Here we have exposed the nucleus of volcanic rock which has been covered over by soft bedded deposits that resemble, like those of Ugi, the muds found in the *Challenger* Expedition to be at present forming around oceanic volcanic islands, whilst the coral limestone only attains any thickness near the coast, and is wanting altogether in the higher regions of the island. At elevations exceeding 400 feet above the sea the coral rock generally disappears from the surface. Above this height it is only found occasionally, 900 feet being the greatest elevation at which I found a fragment. The thickness of the coral limestone does not exceed 100 feet. The soft deposit, which is regularly bedded, the dip varying between 10° and 30°, displays a greater variety in its characters than the similar deposit in the island of Ugi. As a rule it presents to the naked eye no other conspicuous organic remains than the white specks of the more minute Foraminiferous tests and the larger microscopic tests of such species as *Cristellaria calcar*, *C. mamilligera*, and others; but in some localities this deposit becomes highly fossiliferous, when it assumes a more compact texture, and displays to the eye fragments of corals with Pteropod and Lamellibranchiate shells. As shown in the accompanying diagram, the structural history



Ideal section of an island displaying the originally-submerged volcanic peak, the overlying soft deposits, and the encrusting coral limestone.

of this island of Treasury may be readily inferred. An ancient submerged volcanic peak, having been covered by a thickness of some hundreds of feet of deposits, for the most part resembling the muds now being formed around volcanic islands, has by this means and by the movement of elevation been brought up to the zone of reef-building corals. After the coral reefs had become established, the whole structure experienced an upheaval of nearly 1200 feet.

In the island of Alu, the principal of the Shortland Islands, another type of structure is exhibited. This island, which has a breadth of eleven or twelve miles and an elevation of about 500 feet, is composed in its north-west portion of ancient and originally deep-seated volcanic rocks (mostly quartz-diorites), while the greater part of it, together with the off-lying lesser islands and islets, is made up of more recent calcareous formations. In describing its structural history I shall be describing its structure. We have the original land of volcanic formation in the north-west part of the island, from which, as from a neucleus, line after line of barrier-reef has been advanced in a south-easterly direction based on a foundation of Pteropod and Foraminiferous muds, and forming ultimately, as the upheaving movement continued, the large island of Alu, which yet preserves in the ridges of its interior these ancient barrier-reefs now removed far from the coast and elevated some hundreds of feet above the present sea-level. The soft deposit underlying the elevated reef-masses contains in abundance the shells of Pteropods and bivalves, the otoliths of fish, the tests of pelagic and bottom-living Foraminifera, and some simple corals of deep-sea genera. The overlying coral limestone sometimes assumes a chalk-like character, and in the interior of the island it may give place to a Foraminiferal limestone. The characters of these different rocks are described in the second part of this paper. The thickness of the coral limestones in this island is probably under 100 feet. When it caps the upraised island barrier-reefs it does not exceed forty feet; but these regions have been subjected to great denudation.

In the small island of Santa Anna, which is two and a half miles in length, we have an upraised atoll that displays within the small compass of a height of 470 feet the several stages of its growth. There is, in the first place, the originally submerged volcanic peak; then the investing soft deposit which, according to Mr. Murray, has the characters of a deep-sea clay; and over all the ring of coral limestone that cannot far exceed 150 feet in thickness. The interior of this upraised atoll is a closed basin containing a fresh-water lake, the bottom of which lies about a hundred feet below the present sea-level: so the island may be roughly compared to a bowl of fresh water floating on the sea. In the vicinity of the locality where the deep-sea clay was exposed, Lieut. Malan observed a concretionary block of manganese peroxide between one and two cubic feet in size, which, according to Mr. Murray, who examined a typical fragment, is quite similar in characters to the smaller masses obtained in deep-sea soundings. The structural history of this island may be briefly summed up. A submarine volcanic peak, having been invested by a deep-sea clay, was brought up by upheaval to the coral zone. An atoll was established on it, and the whole was subsequently raised to a height of nearly 500 feet above the sea.

Lastly, I come to the large mountainous islands, of which St. Christoval may be taken as the type. This island is more than seventy miles in length, and about 4100 feet in height. It is composed in mass of ancient volcanic rocks, which are flanked on their lower slopes by recent calcareous formations. A fawn-coloured crystalline limestone, containing reef débris, lies directly on the volcanic rock, and is itself overlain by the coral limestone. I did not find these calcareous rocks above 500 feet above the sea; so great has been the denudation of this island that these calcareous formations constitute a much thinner crust than that which came under my notice in the smaller and more recent islands.

Such being the facts, I come now to the four general conclusions, which are as follows:—

1. *That these upraised reef masses, whether atoll, barrier-reef, or fringing-reef, were formed in a region of elevation.*

This is self-evident. The last upheaval that occurred, of which I found proofs in different parts of the group, was to the extent of about five feet; but at the present day there are signs of this movement being still in operation, and, for the purposes of future observation, I have established datum-marks in different islands. This, therefore, being a region of elevation, it is apparent that that portion of Mr. Darwin's theory of coral reefs which ascribes the formation of atolls and barrier-reefs to a movement of subsidence cannot be applied to the islands of the Solomon Group, since we here find upraised atolls and barrier-reefs associated with existing reefs of the same description. This conclusion accords with the results obtained by Prof. Semper in the case of the Pelew Islands, and by Prof. A. Agassiz in the case of the Florida reefs.

2. *That such upraised reefs are of moderate thickness, their vertical measurement not exceeding the limit of depth of the reef-coral zone.* Amongst the numerous islands which I examined I never found one that exhibited a greater thickness of coral limestone than 150 feet, or 200 feet at the very outside. In fact, so great has been the denudation of these islands, where, according to my own

observations, there is an annual rainfall at the coast of 150 inches, that I rarely came upon a thickness of a hundred feet of coral limestone. One of the corollaries of the theory of subsidence is concerned with the great thickness of atolls and barrier-reefs. My observations in this region—and it is such regions that can alone afford such evidence—show that atolls and barrier-reefs can be formed with no greater thickness than they would possess in accordance with the depths in which reef-corals thrive, the vertical thickness of the reef not exceeding the depth of the reef-coral zone. . . . The only objection worthy of attention that had been advanced against the atoll-theory of Mr. Darwin was, in the opinion of Sir Charles Lyell,[1] the circumstance that, as far as was known, no bed or formation of coral of any thickness had been discovered. This objection, which was proposed by Mr. Maclaren in 1842, derives additional force at the present day in the light of my observations in the Solomon Islands.

3. *That these upraised reef-masses in the majority of islands rest on a partially consolidated deposit which possesses the characters of the "volcanic muds" which were found during the "Challenger" Expedition to be at present forming around volcanic islands.*

4. *That this deposit envelops anciently submerged volcanic peaks.*

These two latter conclusions corroborate in a remarkable manner the views, based on the observations of the *Challenger* Expedition, which Mr. Murray has advanced. I will cite the structures of two islands to illustrate these views. In the small island of Santa Catalina I found that the elevated reef was based on volcanic rock with the intervention of a thin brecciated conglomerate. In the island of Treasury I found the volcanic rock covered by a soft, partially consolidated volcanic mud, which attained a thickness of some 300 or 400 feet, and was itself incrusted on the lower slopes of the island by the elevated reef-mass. In the one island, the volcanic peak had been exposed to breaker-action before the reef-corals established themselves. In the other island, the submerged volcanic peak was first brought within the reef-coral zone by the deposition of layers of "volcanic mud" upon it, assisted by the movement of elevation.

With reference to my own bias on this subject, I may here add that during the first eighteen months I passed in the Solomon Islands I was only acquainted with the theory of subsidence, and that after having failed to make my observations harmonise with the theory of Mr. Darwin, I collected my facts with a very confused idea of the direction towards which they were tending. It was therefore a cause of great satisfaction to myself when I first became acquainted with the views held by Mr. Murray.

These calcareous rocks, in the examination of which Mr. Murray used the methods he employed in the case of the deep-sea deposits, may be grouped into two chief classes, according to the proportion of volcanic débris they contain.

The *first class* comprises those rocks which, being largely composed of volcanic débris mixed with the tests of Foraminifera, Pteropods, and other Mollusks, have a composition very similar to that of the volcanic muds at present forming around oceanic volcanic islands in the Pacific. These rocks contain both pelagic and bottom forms of Foraminifera, and four prevailing kinds of them may be distinguished.

1. A friable rock, containing from 5 to 20 per cent. of carbonate of lime, and displaying to the eye only the white specks of minute Foraminiferous tests, with a few of microscopic size, entire Molluscan shells being rarely embedded. The carbonate of lime consists of Coccoliths, Rhabdoliths, Gasteropod, and Lamellibranchiate shells, Echinoderm fragments, calcareous Algæ, and many pelagic and bottom forms of Foraminifera. The residue consists for the most part of the minerals felspar, magnetite, augite, hornblende, fragments of pumice, scoriæ, and other volcanic rocks, with many glassy fragments, and of a fine argillaceous matter which forms about a third of the rock-substance. Rocks of this character form the masses of Treasury and Ugi Islands.

2. A very friable rock, containing from 30 to 35 per cent. of carbonate of lime. These rocks resemble in their general composition the rocks of the previous group, but they differ in the circumstance that they inclose in great numbers the entire shells of Pteropods, Gasteropods, Lamellibranchiates, together with simple corals of deep-sea genera, and the otoliths of fish. There are contained in the residue, in addition to the mineral particles and fine argillaceous material, a great many glauconitic-like casts of Foraminifera. Rocks of this character largely compose Alu, the principal island of the Shortland Islands, and are exposed in the low hills in the rear of Choiseul Bay.

3. A hard, grey fossiliferous limestone, containing usually about 60 per cent. of carbonate of lime and much volcanic débris. Such a rock, which is exposed in the lower courses of the Treasury streams, is chiefly composed of the broken-down fragments of corals and Lamellibranchiate shells, with calcareous Algæ and a few Foraminifera.

4. Coarse-grained rocks composed of the fragments of volcanic and coral rocks in rounded grains. Occasionally larger fragments, together with shells, are imbedded. Such rocks occur on the northern slopes of St. Christoval near the coast.

The *second class* includes those rocks which are largely composed of coral, Molluscan shells, Foraminiferous tests, and calcareous Algæ, with but a small proportion of volcanic débris. The share that each of these four principal constituents takes in the building up of the rock differs widely, and on this basis the following groups have been made. Whether the rock is mainly formed of the massive corals, or whether it is composed of the fragments of such corals broken off by the waves and mixed with shells and other organisms in varying proportions, such a rock as must be forming on the outer slopes of reefs, or whether it is composed of the consolidated calcareous muds and sands which are found at the bottom of lagoons, it has in all cases the same coral origin. The variety in character exhibited in the following groups of coral limestones may be thus in a great measure explained.

1. Coral rocks, properly so-called, which are merely the massive reef-corals in different stages of fossilisation.

2. Coral rocks, which are chiefly made up of calcareous Algæ, fragments of Molluscan shells, corals, and Echinoderms, the interstices being filled up by the tests of Foraminifera and other small calcareous organisms. In the composition of such rocks, which form *the majority of the so-called coral limestones* in the Solomon Islands, coral fragments take only a secondary part. The percentage of carbonate of lime in these rocks varies between 90 and 95, the residue consisting of the common volcanic minerals, siliceous casts of Foraminifera and a fine argillaceous matter.

3. Chalk-like coral limestones, which contain about 95 per cent. of carbonate of lime, and are chiefly composed of the fragments of Molluscan shells, Echinoderms, corals, calcareous Algæ, and Foraminifera. These rocks, therefore, in their general composition resemble the rocks of the second group of coral limestones; but they differ conspicuously in their chalk-like appearance and in being more friable. They occupy the usual surface position of other coral rocks, although not being of common occurrence. I found them overlying the soft Foraminiferous and Pteropod deposit in the Shortland Islands, and they may be sometimes found forming the central elevated portions of existing reefs. One of the specimens of coral this rock contained, according to a determination made

[1] "Principles of Geology," 12th edit. vol. ii. p. 612

by Dr. Leonard Dobbin, a considerable amount of magnesia, and thus approaches a magnesian limestone.

4. Compact fawn-coloured crystalline limestones of a homogeneous texture, in which sometimes reef débris may be observed. These rocks, which are of common occurrence on the lower slopes of the large island of St. Christoval, where they overlie the volcanic rocks of the district, are apparently formed by the consolidation of the ooze found at the bottom of lagoons inside coral reefs.

5. Foraminiferal limestones, which are hard and compact in texture, and are chiefly made up of pelagic and bottom-living Foraminifera, and contain occasionally a few simple corals of deep-sea genera. They contain generally from 75 to 85 per cent. of carbonate of lime, the residue being formed of the common volcanic minerals, siliceous casts of Foraminifera and fine argillaceous matter. These limestones are found at the surface, and in the island of Alu they may be seen to overlie the soft Foraminiferous and Pteropod deposits.

Such are the calcareous formations which are of most frequent occurrence in the Solomon Islands. Three other highly interesting rocks came under my notice, but in each case only in one locality.

(*a*) A Rhynconella limestone. In one of the islets of the Shortland Islands I found a hard grey limestone composed of numbers of Brachiopod, Gasteropod, and Lamellibranchiate shells, with many simple corals of deep-sea genera, embedded in a calcareous matrix largely made up of the tests of Foraminifera (chiefly pelagic forms). The Brachiopod shells belonged to the same species of Rhynconella. Mr. Davidson is inclined to look upon it as the same as *R. Grayii*, a species hitherto represented by a single specimen discovered in the British Museum amongst other natural history objects from the Fiji Islands (?) collected by Mr. J. M'Gillivray more than thirty years since.[1] The simple corals, as Mr. Quelch informs me, belong to the deep-sea genera, Leptocyathus, Stephanophyllia, Odontocyathus, Flabellum, &c. The Gasteropod and Lamellibranchiate shells are, as I learn from Mr. E. Smith, of shallow-water habit. This limestone contained 75 per cent. of carbonate of lime, the residue being made up of the common volcanic minerals, reddish siliceous casts of Foraminifera, and fine washings.

(*b*) A friable earthy rock, which, from the small size of the minerals, the absence of bottom-living Foraminifera, and the scarcity of pelagic forms, resembles a deep-sea clay, and contains a thin coating of manganese between the small layers or folds of the rock. This deposit, which contains about 20 per cent. of carbonate of lime, occurs in the upraised atoll of Santa Anna underneath the elevated reef-mass. On the reef-flat in the vicinity of this deposit there was observed by Lieut. Malan, as already observed, a detached concretionary block of manganese peroxides, one to two cubic feet in size: a typical fragment that I brought home is, according to Mr. Murray, quite similar to smaller masses dredged by the *Challenger* and *Blake*.

(*c*) A hard Foraminiferal limestone, chiefly composed of pelagic Foraminifera. Of this rock, which was found at the surface in Treasury Island, Mr. Murray observes that the organisms, together with the minerals, are similar to those found in deposits of modern seas near volcanic islands at depths of from 500 to 800 fathoms. The Foraminifera are identical with those found in the surface-waters of the tropics at the present day.

With such data as the foregoing at my disposal, it might appear an easy matter to gauge the amount of elevation that has occurred in these regions in recent times. But so great has been the sub-aërial denudation in these islands that although the elevatory movements have brought up to our view a deep-sea clay, with its concretion of manganese, and a Foraminiferal limestone that was probably formed in a depth of from 500 to 800 fathoms, two rocks which occur in islands at opposite extremities of the group, yet, notwithstanding this great upheaval, the calcareous envelopes usually disappear from the slopes of the volcanic islands at heights of 500 or 600 feet above the sea, and never came under my observation in such islands at greater elevations than 900 feet. The rainfall in the elevated interior of the large islands cannot be much under 300 inches in the year, since my own observations place it at about 150 inches at the coast. Of the rapid degradation of the surface which these calcareous districts undergo during a heavy fall of rain, of as much as two to three inches in the same number of hours, I was a frequent witness. In a few minutes the whole hill-slope discharges a continuous sheet of muddy water, the rivulets swell to turbid streams, and the water rushes down the permanent courses with the roar of a mountain torrent. After the rain-storm has passed away, the band of muddy water that fringes the whole length of the coast, to a distance of one-quarter or one-third of a mile from the shore, indicates the loss of material which the land-surface has sustained.

From the general character of these calcareous formations it may be safely inferred that they will be found wherever there has been elevation during the recent period in regions where coral reefs are flourishing. Amongst other localities we may look to the West Indies, the Indian Archipelago, New Guinea (more particularly the south-coast), New Britain, New Ireland, the Santa Cruz Group, the New Hebrides, the Loyalty Islands, New Caledonia, and the Fiji and Tonga Groups, as likely to possess at the sea-border formations of a similar character. In the Solomon Islands, many other islands, such as Ulaua and Ronongo, will be probably found to be counterparts of the islands of Ugi and Treasury.

NOTE.—A reference should be made to the occurrence of worked flints of the palæolithic type in the soil of the cultivated districts of these islands. The natives say they have fallen from the sky, which reminds one of a similar superstition prevalent in the country districts at home as to the source of celts. I was never successful in finding where they came from originally, and would recommend future visitors to this group to pay attention to this point. They are said to occur together with a chalk-like rock on the beaches of Ulaua, an island which I was unable to visit. (For further information on this subject, *vide* some notes of my own read by Prof. Liversidge before the Royal Society of New South Wales, *Journal* for 1883, vol. xvii. p. 328.)

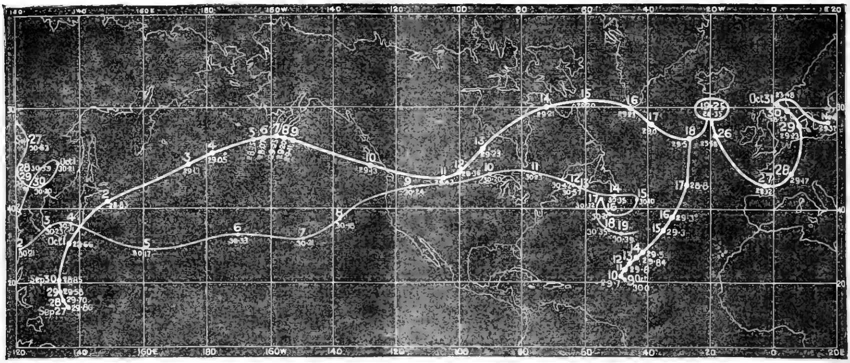
TRACING A TYPHOON TO EUROPE

AT the meeting of the Royal Meteorological Society held on November 18, a paper by Mr. Henry Harries, on "The Typhoon Origin of the Weather over the British Isles during the second half of October, 1882," was read. The author had prepared daily charts of the North Pacific Ocean from September 26 to October 10, and by permission of the Meteorological Council the charts of the area between the western coast of America and Eastern Europe were utilised. The earliest evidence of the formation of the typhoon was on September 27, some distance east-south-east of Manilla. At first the movement was towards north-west, 5 miles an hour, but on September 30, when the storm-area extended to 1300 miles north-west of the centre, it curved towards north-east, crossed the south-eastern corner of Japan at 33 miles an hour, and attained a maximum rate of 51 miles per hour on October 2 to 3, after leaving the Japanese coast. In the neighbourhood of the Aleutian Archipelago the progress was very slow until the 9th, when it rapidly increased to 35 miles an hour, and entered Oregon on the 10th. The Rocky Mountains proved to be no obstacle to the progress of the typhoon, which crossed the range at $36\frac{3}{4}$ miles an hour, and, maintaining this rate, passed across the Northern States into Canada. Thence it crossed Hudson's Bay and Labrador, into Davis Strait. Altering its course to south of east it passed the southern point of Greenland on October 16, and two days later, in lat. 55° N., long. 27° W., it was joined by another disturbance, which seems to have formed about October 9 in 20° N., 48° W. The junction of the two storms was followed by a complete cessation of progressive movement for a week (October 19 to 25), and it was during this period was formed as a subsidiary the gale which suddenly arrived over our south-eastern counties upon the morning of October 24, completely upsetting the Meteorological Office forecasts of the previous night The author quoted several records from ships, which went to show that this secondary storm had not formed until nearly midnight; and that reports from outlying coast-stations would not have enabled successful forecasts to be issued before 3 a.m. on the 24th. The 8 a.m. observations for the Daily Weather Report show that with the exception of Hurst Castle the winds on the northern side of the Channel were moderate, but along the French coast heavy gales were blowing. Ships' records indicate that off Start Point a moderate easterly gale began at 6.20 a.m. By 8 a.m. a whole gale from S.E. was blowing



Tracks of the Typhoon and Anticyclone of September and October 1882. The thick line shows the track of the typhoon, the thin line that of the anticyclone. The dates and the lowest and highest ascertained readings of the barometer for the day being given near the positions of the centres at Greenwich noon.

to south-west of Portland, while off the Start at 8.30 a.m. the wind veered to W.N.W. a strong gale. At 9 a.m. the wind off Portland veered to W. and blew with terrific violence. Further east, as far as the Downs, the wind had by noon changed to W. and S.W., and increased to a furious storm, with violent squalls and a terrible sea. As this gale passed away the primary moved into the Bay of Biscay and entered France on the 27th. As in Japan and America, its advance was marked by violent gales and destructive floods over a very extensive area—from Algeria northwards. The damage caused by the floods in England was serious, but trifling compared with the losses in Southern and Central Europe, the destruction being enormous. This typhoon was the principal contributor in making October, 1882, by far the worst within living memory. With this final effort it seemed to have expended its fury, and in crossing France and the Netherlands it gradually filled up. The last trace of the typhoon was in the Baltic on November 1, when it quietly dispersed, after covering over 14,000 nautical miles in thirty-six days, the longest track hitherto followed day by day.

THE NIVAL FLORA OF SWITZERLAND

In the spring of 1883 (the last year of his life), the eminent Swiss naturalist, Prof. Oswald Heer, having finished his "Flora fossilis Arctica," resumed a work with which he had been long occupied before—viz. the preparation of a Nival Flora of Switzerland, in which he proposed to give an account of all the plants found above 8000 feet in that country, and a comparison of these with the Nival flora of other countries. This work, based on very abundant material, was nearly completed before the author's lamented death;—he anticipated being able to finish it in about eight days more had health allowed. The work has now been published in full (as he left it) in the *Nouveaux Mémoires de la Société Helvétique des Sciences Naturelles* (vol. xxix. part 1). The summary of results of this research, which were communicated at a gathering of Swiss naturalists in Zurich, we will here reproduce.

(1) We know at present in Switzerland 337 species of flowering plants which have been observed at from 8000 to 13,000 feet above the sea; 12 of these species have still been found above 12,000 feet.

(2) All these species are found in the lowest division of the Nival region, 8000 to 8500 feet. Above 8500 feet there is no species which is peculiar to this height.

(3) One-tenth of the species of the Nival region consists of species of lowland flora, nine-tenths of mountain plants. Most of the latter belong to the Alpine region, and about a quarter of the species has its greatest distribution over 8000 feet. These are the Nival plants in the narrower sense. While the lowland plants and the plants of the hilly and sub-Alpine region disappear at about 9500 feet, the Nival plants, with a few Alpine species, are the last children of the flora.

(4) The mountain mass of Monte Rosa has the richest Nival flora; which here rises higher than in the Rhætian Alps, and in the latter higher than in the Glärnisch Alps.

(5) The majority of the species are distributed throughout the whole region of the Alps; only a small portion is found exclusively in the east from Orteler to the Gothard, or in the west from the Gothard to Savoy.

(6) About half of the plants of the Nival region come from the Arctic zone, and very probably came over Scandinavia to our region in the Glacial period, since Arctic Europe has the largest number (140) of species

which our Nival flora has in common with the Arctic zone.

(7) This Arctic flora probably arose on the mountains of the Arctic zone, and stood in the same relation, in the Miocene period, to the flora of the Arctic lowland as the present Alpine flora to the flora of the Swiss lowland.

(8) The Miocene Arctic flora advanced to Europe in the Tertiary period, and the European Tertiary flora received from it the types which now characterise the temperate zone, viz. the pine-woods and foliage-trees with deciduous leaves. In course of time these dominated more and more over the tropical and sub-tropical forms, which were the original occupiers of these regions, and became the mother-plants of a portion of the present lowland flora.

(9) In the Glacial period the mountain plants of the Arctic zone descended into the lowland, and spread southwards with the glaciers. As in the Tertiary period the trees and bushes with deciduous foliage wandered southwards, so in the Glacial period did the mountain plants; and that this migration took place radially from the north is proved by the fact that not only in the snow region of our Alps nearly the half of the plant species consists of Arctic species, but also the American mountains, and on the other side the Altai, and even the Himalaya, have quite a number of such Arctic species, and have them in common with the Swiss Alps. We know that already in the Tertiary period, and also in the period of the Upper Cretaceous, a number of plants can be traced from Greenland on to Nebraska, in North America, and on the other hand to Bohemia, Moravia, and on to Southern Europe. Thus in the period of the Cretaceous formation, in the Tertiary, and in the present formation, we find the same phenomenon: that Europe with America has a number of species in common which were formerly indigenous in the Arctic zone, and therefore very probably went out from that as their original home. The same process is thus repeated in different ages; the plant-world of the high north has at all times exercised a great influence on the formation of the plant-covering of Europe.

(10) The endemic flora of the Nival region arose in our Alps. A principal centre of its formation seems to have been the Monte Rosa chain, in which probably, even during the Glacial period, extensive mountain masses of ice and *névé* were liberated.

(11) This flora received at the beginning of the Quaternary period its present character, and spread on the moraines of the glaciers into the lowland and into the mountainous regions of the neighbouring countries.

(12) Its mother flora had probably its abode in the Tertiary mountain country of Switzerland.

NOTES

We understand that the post of Assistant Director of the Royal Gardens, Kew, has been offered to Mr. D. Morris, M.A., F.G.S., the Director of Public Gardens and Plantations, Jamaica. The appointment is in the gift of the First Lord of the Treasury.

So much has been heard during the last few years of the services rendered to the science, industry, and commerce of the West Indies by the public gardens and Government plantations of Jamaica under the superintendence of Mr. Morris, that it is with surprise and regret that we learn that the future efficiency of these institutions is seriously threatened. A Select Committee, it appears, was recently appointed, under a resolution of the Council of Jamaica, "to consider the means of diminishing the expenses of the Government," and, among other suggestions and recommendations, it proposed that the Government cinchona plantations should be sold, and that the public gardens at Kingston should be handed over to the local authorities of that town to be maintained by them, instead of, as heretofore, by the Government, under the Director of Public Gardens. Committees appointed under these circumstances are generally more anxious to justify their existence by making recommendations than careful to inquire where they would be always possible or desirable. The cinchona plantations, thus threatened with extinction, were founded in 1868 by Sir John Peter Grant, and now consist of 150 acres under cinchona, with smaller areas under jalap, tea, and nurseries for timber and shade trees. According to the "Handbook of Jamaica," they distributed in five years to private planters 1200 ounces of cinchona-seed, 1,200,000 cinchona seedlings, 400,000 cinchona plants, besides large quantities of timber and shade trees for re-foresting purposes. The Kingston Gardens, which are to be taken from under Mr. Morris's control, are used as a depot for plants from the other establishments, and also as the centre of distribution of plants and seeds to all parts of Jamaica and of the West Indies; there is no doubt, therefore, that they fulfil important functions.

If there was a single department in the whole Government service on which West Indian economists should have refrained from laying their hands except by way of increasing its scope and efficiency, we should have thought Mr. Morris's department that one. For if the West Indian Islands are ever to emerge from the disastrous economical condition of the past thirty years, and regain their previous flourishing state, it will be by the labours of institutions such as the public gardens, and of men such as Mr. Morris. Their old staples are useless to them, for Europe can buy them cheaper in other markets, and they must find new ones, or plunge deeper into the mire of financial embarrassment and bankruptcy, public and private. This can only be done by experiments and careful observations which no one but a public department and skilled botanists can carry out. Happily the economic value of the gardens in Jamaica have been recognised by the highest authorities. The Royal Commissioners stated that the department was invaluable, and that it was in as good a state as the sums placed at Mr. Morris's disposal would allow. The Governor coincided in this testimony, and added that "Mr. Morris was untiring in his endeavours to induce persons to commence new industries calculated to develop the resources of the island, and to bring about a condition of prosperity which would go far to counterbalance the depression under which the sugar industry of Jamaica now labours." It may be hoped therefore, notwithstanding the report of the Committee on Government Economy, that the department may be permitted to pursue its "invaluable" work on the same lines and with undiminished means.

Mr. Samuel Birch, D.C.L., LL.D., F.S.A., Keeper of the Egyptian and Oriental Antiquities in the British Museum, died, on the 27th inst., in his seventy-second year. Dr. Birch had served in the British Museum for fifty years, during the last part of which he was in charge of the Egyptian and Assyrian antiquities, and it is with this department of Oriental scholarship that his name will ever be associated. His early writings of nearly fifty years ago dealt mainly with Chinese subjects, and one of his first duties at the British Museum was to catalogue the large collection of Chinese coins, and throughout the greater part of his life he manifested his interest in Chinese subjects by various publications. He was twice despatched to Italy on archæological missions on behalf of the Government, and in 1860 founded the Society of Biblical Archæology. His works on all departments of Egyptology fill many volumes, and extend over more than forty years, and at the time of his death he had in the press one work, while another, a new dictionary of hieroglyphics, was nearly completed.

No authentic information is to hand yet to explain the terrible and disastrous colliery explosion at the Mardy mine last week. The atmospheric pressure had been unusually high, and so far as we have been able to gather, coal-dust played an important part in the explosion. No doubt some facts as to the condition of the mine will come out at the inquest on January 12.

THE following are the arrangements for the Friday evening lectures at the Royal Institution before Easter:—January 22: Prof. Tyndall, F.R.S., Thomas Young and the Wave Theory; January 29: Sir William Thomson, F.R.S., Capillary Attraction; February 5: T. Pridgin Teal, F.R.C.S., The Principles of Domestic Fireplace Construction; February 12: Prof. Osborne Reynolds, F.R.S., Experiments showing Dilatancy, a Property of Granular Material, Possibly Connected with Gravitation; February 19: W. K. Parker, F.R.S., Birds, their Structure, Classification, and Origin; February 26: A. A. Common, F.R.S., Photography as an Aid to Astronomy; March 5: Prof. Alexander Macalister, F.R.S., Anatomical and Medical Knowledge of Ancient Egypt; March 12: Reginald Stuart Poole, Corresp. Inst. France, The Discovery of the Biblical Cities of Egypt; March 19: W. H. M. Christie, F.R.S., Astronomer Royal, Universal Time; March 26: Wm. Chandler Roberts-Austen, F.R.S., M.R.I., Chemist of the Mint, on Certain Properties Common to Fluids and Solid Metals; April 2: Howard Grubb, F.R.S., Telescopic Objectives and Mirrors—their Preparation and Testing; April 9: William Anderson, M.Inst.C.E., New Applications of the Mechanical Properties of Cork to the Arts; April 16: Prof. Sir Henry E. Roscoe, M.P., F.R.S.

WE regret to learn that Dr. W. Sklarek, who founded *Naturforscher* eighteen years ago, and has conducted it since, has resigned the editorship of that well-known journal, which will now be published by the Laupp'schen Buchhandlung, Tübingen. Dr. Sklarek, we understand, will edit a new journal of a similar kind to be published in Brunswick.

IT is stated that experiments are being made at Prof. Lieben's chemical laboratory at Vienna, with a new gaslight invented by Dr. Auer. A cotton wick, saturated with an incombustible metal solution, is introduced into the flame of an ordinary Bunsen lamp, the result being a light similar to the incandescent electric light.

MR. LESLIE STEPHEN'S "Life of Henry Fawcett," just published by Messrs. Smith, Elder and Co., contains two very characteristic letters from Darwin, which now see the light for the first time. Mr. Stephen refers to the deep impression made on Fawcett's mind by the "Origin of Species." He became an enthusiastic Darwinian, and in December 1860 published an article in which "he states with his usual firmness the true logical position of Darwin's theory; distinguishing carefully between a fruitful hypothesis and a scientific demonstration; exhibiting the general nature of the argument and the geological difficulty with great clearness, and taking some pains to prove that religion is in no danger from Darwinism." This led to a correspondence with Darwin, and in one of the letters the latter, after referring to his satisfaction at hearing that Mill considered his book a piece of thorough logical argument, adds:—"Until your review appeared I began to think that perhaps I did not understand at all how to argue." In a second letter, dated September 18, 1861, thanking Fawcett for a paper of his read before the British Association, Darwin writes:—"You will have done good service in calling the attention of scientific men to means and laws of philosophising. As far as I could judge by the papers, your opponents were unworthy of you. How miserably A talked of my reputation, as if that had anything to do with it. How profoundly ignorant B [who had said that Darwin should have published facts alone] must be of the very soul of observation! About thirty years ago there was much talk that geologists ought only to observe and not theorise; and I well remember some saying that at this rate a man might as well go into a gravel-pit and count the pebbles and describe the colours. How odd it is that any one should not see that all observation must be for or against some view if it is to be of any service!" Referring to his health Darwin says he is one of those miserable creatures who are never comfortable for twenty-four hours; "and it is clear to me that I ought to be exterminated." Again he says that to him "observing is much better sport than writing." Referring to the timidity with which men of science received his theory, he wrote: "The naturalists seem as timid as young ladies should be, about their scientific reputation." The whole of the correspondence at this time (1860-61) between Darwin and Fawcett, of which Mr. Stephen only gives the two letters here quoted, should be of very great general interest.

THE Vienna Correspondent of the *Times* reports that Dr. Gautsch, the new Minister of Public Instruction in Austria, has prohibited the use of paper ruled in square or diagonal lines within all public schools. The reason of this is that such paper has been found to injure the eyesight of pupils. It has been largely used hitherto in primary schools to facilitate writing and arithmetic lessons; but in future only paper plain or ruled in straight lines is be used.

A STRIKING case of vital resistance in fishes has been lately reported by M. Douaret de Bellesme, Manager of the Aquarium of the Trocadéro in Paris. On November 18 a fishmonger, M. Heydendare, received from Gonda (the centre of fisheries in the region about Rotterdam) a large consignment of fishes packed and preserved in ice. They could not have been caught later than the 16th, and were probably caught on the 15th. On unpacking, a jack was seen to move its gills slightly, and the idea occurred to wash it with fresh water, and immerse it in a vessel. In a few hours the fish was in its normal state, and very lively. M. Heydendare sent it to the Trocadéro Aquarium, where it is to be seen now; it is a fine animal, about 2 feet 4 inches long. Here, then, is a case of a fish out of water more than forty-eight hours (probably three days), packed with little care, along with dead fish and pieces of ice—travelling thus 280 miles, and coming to life again. The lowering of temperature was doubtless very favourable to maintenance of the vital functions.

THREE tall chimneys belonging to Kunheim and Co., of Berlin, were lately destroyed by means of gun-cotton. The largest was about 147 feet high, and 10 feet diameter at the base. In order that it should fall outwards from the city, the charge of gun-cotton (about 57 lbs.) was attached in portions to the side next the city, and to the adjacent sides. All three were exploded simultaneously with a magneto-electric apparatus. The chimney, instead of falling obliquely, collapsed vertically, and on inspection the four walls of the pedestal were found to have been driven outwards. The bricks were all detached from each other, and nearly all entire. The debris was thrown a very little distance. The two other chimneys, treated similarly, fell as was expected, *i.e.* obliquely away from the city. One of them, in falling, broke in two about the middle.

RECENT issues of *Globus* contain two most interesting articles on the investigations into the antiquities of the I land of Bornholm, carried on for a considerable period by its former chief official, Herr Wedel. The Stone Age is extensively represented, although kitchen-middens appear to be wholly absent, by graves, stone coffins, and other objects. The first contain unburnt, as well as the remains of cremated, bodies, but the latter are found under such circumstances as to lead to the conclusion that they belong to a later period. With the exception of stone chisels, all the objects usually found in graves belonging to the Stone Age are found, such as axes, arrow-heads, and the like. Amber ornaments also frequently occur. The stone coffins, which are sometimes very large, are also numerous, and in the mounds with them are frequently found the bones of cremated bodies. On this question, Herr Wedel comes to the conclusion that cremation in Bornholm must have been introduced towards the close of the Stone Age. Most of the objects were apparently made in the island itself; but it is not improbable that the larger flint articles, or possibly the blocks from which they are made, come from places where flint is more plentiful than in Bornholm. Traces of houses belonging to this age have also been found. On the whole, the island during this period does not appear to have been thickly populated; the people moved hither and thither, and appear to have had domestic animals. The remains of the Bronze Age are also very numerous and interesting; of these a full account is given, and it is interesting to notice that, during this period, cremation appears to have been the usual method of disposing of bodies of the dead. Similarly, the finds belonging to the Iron Age are described, and, in conclusion, the writer says that in Bornholm we can trace, without important breaks, human development from the Stone Age down to historic times. Nothing appears, he says, in this long history to show that there was any sudden alteration in the growth of civilisation such as might be caused by the influx of a new tribe. Such an influx, had it taken place, would certainly have left recognisable marks behind it; and, indeed, the thick population of the island in the Bronze and earlier Iron Ages left no opportunity for the settlement of any external people in Bornholm.

The method of placing electric lamps in front of locomotives to illuminate the line, has been tried on many lines, but apparently has not found much favour. Recent experience in Russia appears to show that financial considerations are not alone unfavourable to the system. On the railway between St. Petersburg and Moscow several locomotives were fitted with electric lamps. For a time they gave great satisfaction, lighting the way more than a kilometre in front. But the *employés* began to complain of the contrast between the lighted and the unlighted surfaces painfully affecting the eyes; and doctors ere long reported that there had been several cases of grave injury to the eyes in this way. Hence the lamps were abandoned. The directors have not, however, given up the idea of better illumination of the line, and they now contemplate placing electric lamps so as to illuminate about 1 kilometre on either side of the station.

The best plant at present known for consolidating, by the interlacing of its roots the loose soil of a newly-made embankment is, according to M. Cambier (of the French Railway Service), the double poppy. While the usual grasses and clovers need several months for the development of their comparatively feeble roots, the double poppy germinates in a few days, and in two weeks grows enough to give some protection to the slope, while at the end of three or four months, the roots, which are 10 or 12 inches long, are found to have interlaced so as to retain the earth far more firmly than those of any grass or grain. Though the plant is an annual, it sows itself after the first year, and with a little care the bank is always in good condition.

According to an official statement issued by the Japanese Government, there occurred 553 earthquakes during the nine years and six months preceding December 1884, averaging one earthquake for every six days and six hours. This must, however, refer to the capital and the surrounding district only, and earthquakes of great violence can alone be counted, for Prof. Milne was able to trace an average of an earthquake per day in Nagasaki, in the extreme south of the Japanese archipelago. The official statistics, on the other hand, may possibly be compiled from the returns of local officials all over the country, in which case only those shocks which caused loss of life or damage to property would be included. If this hypothesis is correct, we should have an average of more than an earthquake per week which was so violent that it caused injuries to life or property sufficiently serious to attract the attention of the local authorities, and, in their judgment, to require a report to the central Government.

M. Herzen contributes to a recent number of the *Revue Scientifique* an account of certain experiments which he made recently on the thermic sense in animals. His observations on man had already led him to the conclusion that impressions of heat are conveyed to the brain by the gray substance of the spinal marrow. Animals, he found, on the other hand, do not react under the impressions of moderate heat, and when the latter is excessive the reaction is one of pain, not of the specific sensation of heat. On the contrary, however, cold operates on them actively, and M. Herzen succeeded in demonstrating by his experiments that impressions of cold in animals are really conveyed by the medullary rays which transmit the impressions of touch. The various experiments which are briefly described in the article satisfied him that the cortical lesions which destroy sensibility to touch also destroy that of cold, and, when the first is preserved, the latter likewise remains; and that, in brief, impressions of contact and of cold are transmitted in the same way to the same regions of the cortical layer of the hemispheres.

In a recent article on the work of the Asiatic Society of Bengal, originally founded by Sir William Jones, during the first century of its existence, we referred to the division of its publications into literary and scientific, the numbers of the *Journal* of the Society in each case being quite distinct. We have now before us the scientific numbers of the *Journal* for the past year, and they show remarkable activity. It should be remembered that there are independent societies in Madras and Bombay, so that the Bengal Society's publications represent the work of one Presidency only. Amongst the scientific papers published during the year are the following:—The theory of the winter rains in Northern India, by Mr. Blanford, the President of the Society, and the Meteorological Reporter to the Government of India; descriptions of some new Asiatic diurnal *Lepidoptera*, chiefly from specimens contained in the Indian Museum in Calcutta, by Mr. Frederic Moore; a new species of *Simulium* from Assam, by Dr. Becher, of Vienna; variations of rainfall in Northern India during the sun-spot period, by Mr. Pearson, the Meteorological Reporter for Western India; a description of a new Lepidopterous insect belonging to the Heterocerous genus *Trabala*, by Mr. Moore; *Phyllothelys*, a remarkable genus of *Mantodea*, from the Oriental region, by Prof. Wood-Mason; notes on the Indian *Rhynchota*, by Mr. Atkinson; a list of Lepidopterous insects collected in Cachar, by Mr. Moore (the first part, dealing with *Heterocera*, has alone been published so far); revised synopsis of the species of *Chæradodis*, a remarkable genus of *Mantodea*, common to India and tropical America, by Prof. Wood-Mason; and finally, an account of the two remarkable south-west monsoon storms in the Bay of Bengal in 1883, by Mr. Eliot, the Meteorologist to the Bengal Government. It should be added that these papers are, where necessary or desirable, copiously illustrated.

It is interesting to note that the various species of Salmonidæ at the Aquarium, South Kensington, have been recently spawned by artificial means, the sea trout being crossed with the Gilleroo and Levenensis trout. A very large yield of ova was obtained, all of which presented signs of healthiness and complete impregnation. Although the fish spawned have been in captivity for four years, they shed their eggs with the same ease as those subjected to natural conditions.

A LARGE number of Salmonidæ eggs are being incubated at the Buckland Museum. It will be remembered that fish-hatching operations were carried out extensively here by the late Frank Buckland, but after his death they subsided, and until this year the apparatus used by him were not called into use. The re-introduction of this feature will afford much gratification to visitors, and especially to those having the interest of the great naturalist's collection at heart. Besides, the authorities have, by this act, shown their sympathy with fish-culture, and have also set an example which might be emulated by the public elsewhere. It may not be generally known, but the Museum does not contain nearly all the exhibits comprised in the Buckland Collection, which cannot be adequately shown to the public in the limited space allotted to the exhibits.

THE Dutch Government has instituted Christmas telegraphic messages at a reduced rate, containing merely the name and address of senders and receivers.

THE numbers of that valuable periodical, the *Indian Antiquary* for 1885, though of course mainly occupied with papers on the special field of Indian scholarship, contain also many of general scientific interest. Thus a considerable space is devoted to folk-lore: there are four papers on the folk-lore of Southern India; one on that of Western India; a paper on the omens from the falling of house-lizards, which is curious from the minuteness with which every part of the body, even the smallest, on which a lizard could fall is provided with its appropriate omen, that for men and women being different. The modes by which evil omens may be averted are added. There is also a selection of Kanarese popular ballads. There are also two learned articles by Prof. V. Ball, in which he seeks to identify the animals and plants of India which were known to early Greek authors. One result of his interesting investigations (as indeed of all similar investigations into the works of early writers, Marco Polo, for example), is to show that most of the statements of these writers, usually ridiculed as extravagant or fictitious, rest on substantial bases of fact.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. A. Murray; an American Robin (*Turdus migratorius*) from North America, presented by Mr. A. Saunders; two Hybrid Ruddy Sheldrakes (between *Tadorna rutila* and *Chenalopex ægyptiaca*), bred in France, deposited; a Sing-Sing Antelope (*Cobus sing-sing* ♂) from West Africa, received in exchange.

OUR ASTRONOMICAL COLUMN

EFFECT UPON THE EARTH'S MOTION PRODUCED BY SMALL BODIES PASSING NEAR IT.—Prof. H. A. Newton has published a paper on this subject in the *American Journal of Science* for December, 1885. He points out that the space through which the earth travels is traversed also by small bodies or meteoroids. The impact of these bodies upon the earth and the consequent increase of the earth's mass have their effect upon the earth's motions both of rotation and revolution. The moon's orbit and the length of the month likewise suffer change. Prof. Oppolzer (*Astron. Nachrichten*, No. 2573) has considered the amount of these actions, and has computed the density which the meteoroid matter must have in the space which the earth is traversing in order to account for the observed and unexplained acceleration of the moon's mean motion. But a body that passes near the earth has also an action of like character by reason of the attraction of gravitation alone, and the conclusion at which Prof. Newton arrives is that these latter bodies do not have an effect at all comparable with that produced by those which actually come into the earth's atmosphere. In fact his investigation shows that the effect upon the earth's motion of the meteors that come into its atmosphere exceeds at least one-hundredfold that of the meteors that pass by without impact.

THE TEMPERATURE OF THE SURFACE OF THE MOON.—Two important memoirs on this subject have recently been published in a separate form. Of these the first is one by the Earl of Rosse and Dr. Otto Boeddicker on "The Changes of the Radiation of Heat from the Moon during the Total Eclipse of October 4, 1884," communicated to the Dublin Royal Society. It will be remembered that Dr. Boeddicker gave a summary of his observations in a communication to NATURE, vol. xxx. p. 589, and stated that the minimum of heat was observed later than the minimum of light. As, however, the diminution of heat was very rapid, and amounted to $\frac{89}{90}$ of the entire amount received from the unobscured full moon, the conclusion from these observations would appear to be that the amount of heat radiated to us from the moon itself as distinguished from that merely reflected or diffused by it, is almost insensible.

The second memoir is by Prof. Langley (the conclusions of which will be found on p. 211), and was communicated to the American National Academy of Sciences, October 17, 1884. It commences with a review of previous researches, Lord Rosse's papers being carefully summarised. The diathermancy of glass for solar and lunar rays respectively, is next investigated, and it was found, as Lord Rosse had previously done, that a much larger percentage of the solar than of the lunar rays was transmitted through glass. Prof. Langley next endeavoured to ascertain whether this effect was due to a general absorption resulting in a heating of the moon's soil with a consequent radiation of heat of a much lower refrangibility than that received, or to a *selective* absorption by the moon of the more refrangible rays. His observations convinced him that the latter condition prevails to a remarkable extent, so that there is "a preponderance in the lunar spectrum of the rays of long wave-length, and hence a tendency to cause a smaller percentage of lunar rays to be transmitted by glass than of solar, and this independently of any effect from heat re-radiated by the lunar soil."

It had been generally assumed, prior to Prof. Langley's bolometer researches, that our atmosphere was most transparent to the visible portion of the spectrum. Prof. Langley has shown, on the contrary, that the coefficient of transmission steadily increases towards the extreme infra-red, up to the point $\lambda = 3\mu$, where the solar spectrum ceases to give any further evidence of its existence. The present research seems to show that this sudden termination of the spectrum is not due to our atmosphere, for Prof. Langley has been able to form a heat-spectrum from the lunar rays, which he is able to trace considerably further in the longer wave-lengths than that of the sun. This lunar spectrum shows two maxima, one fairly corresponding with "the solar curve maximum, the second indefinitely lower down in the spectrum, corresponding to a greater amount of heat at a lower temperature." This latter portion of the spectrum Prof. Langley considers as being clearly due to the moon itself, and as revealing its real temperature. This temperature, he concludes from his study of the spectra of cold bodies, is lower than that of melting ice. In a further paper read before the National Academy in November last, Prof. Langley states that a comparison of the spectra obtained from the moon in summer with those obtained in winter, shows that a much greater amount of heat is received in the latter season than the former, a difference probably due to the greater amount of aqueous vapour in our atmosphere during summer. He also mentions that he has made the first attempt to determine the temperature of space by direct experiment.

NEW COMET.—A telegram from Prof. Krueger, Kiel, announces the discovery of a new comet by Mr. W. R. Brooks, Red House Observatory, Phelps, New York. The following places have been obtained at the Harvard College Observatory:—

Meteor Showers

Meteors have been observed during this week in former years from the following radiants:—Near β Aurigæ, R.A. 93°, Decl. 43° N.; R.A. 145°, Decl. 5° N.; R.A. 150°, Decl. 67° N.; and R.A. 181°, Decl. 35° N.

GEOGRAPHICAL NOTES

THE current number of *Petermann's Mittheilungen* contains an account of Herr Menge's second journey in the Somali Peninsula, accompanied by an excellent map showing the courses of both journeys. The traveller's meteorological observations and measurements, worked out by Dr. Schmidt of Gotha, are appended to the paper. Dr. Paulitschke's account of his journeys to Harar and amongst the Northern Gallas is concluded in this number. It contains a mass of interesting information of all descriptions with regard to this region. In an appendix a sketch is given of the scientific results of the journey, arranged under the heads—astronomical and magnetic observations, topography, anthropology and ethnography, and natural history.

THE *Bulletin* of the Paris Society of Geography just published (3e trimestre, 1885) contains the full text, with maps, of Dr. Heis's journeys amongst the Laos. M. Errington de la Croix, under the title of "Seven Months in the Tin Country," describes the method of working the tin-mines of Perak, in the Malay Peninsula. The only other paper in the number is one of great interest by M. Pinast on certain explorations of his in the State of Panama, especially in the regions around the Chiriqui lagoon, and the districts inhabited by the Guaymi Indians.

THE last Ergänzungsheft, or supplementary number of *Petermann's Mittheilungen*, is a lengthy account by Dr. Boas of his journeys during 1883 and 1884 in Baffin Land. It is divided into four main parts: an account of the journey from day to day, worked into a narrative; the history of past discoveries in the same region; geography; and, lastly, anthropo-geography. One appendix contains a long list of Eskimo place-names in Baffin Land, with their meanings; another gives a number of astronomical observations at various stations. The work is accompanied by two maps, one of Cumberland Sound and Cumberland Peninsula; the other represents the distribution of Eskimo tribes in Baffin Land.

THE current number of the *Proceedings* of the Vienna Geographical Society (Bd. xxviii. No. 11) contains a paper entitled "Shamanism in Upper Austria," by Dr. Zehden. The district specially referred to is the wide granite plateau which forms the watershed between Bohemia and Upper Austria, and the paper describes the old superstitions and practices still surviving amongst the comparatively primitive people who inhabit the district. The application of the term "Shamanism" to these in the bulk is curious, and somewhat questionable. Shamanism is the form of Buddhism ("Northern Buddhism") prevailing amongst the Mongols and Thibetans, the *Shaman*, or priest, being one who has overcome all his passions. It is said to be a word of Hindu origin. The Pope of this sect, which differs from the Buddhism of India and Ceylon more in state and power than in doctrine, is the Dalai Lama at Lhassa. It has an enormous literature, which is described as the dreariest in existence. Like every other form of religion, and perhaps more than most religions of civilised peoples, it has its superstitious practices and beliefs; but there appears no more excuse for transferring this name from Thibet and Mongolia to Austria, and applying it to superstitions there, than for calling the latter Babylonian, Chaldean, or something else that has no connection whatever with them. The number also contains further letters from Dr. Lenz, in charge of the Austrian expedition to the Congo.

A TELEGRAM was received in Berlin on the 27th inst., announcing the death of Dr. Büttner, a German explorer travelling in Bonnyland, in Africa. The deceased, like Livingstone, was formerly engaged in missionary work in South Africa.

TEMPERATURE OF THE SURFACE OF THE MOON

IN a memoir on this subject presented to the U.S. National Academy of Sciences by Prof. S. P. Langley, the author concludes by reviewing as follows our sources of information, and weighing the imperfect and contradictory results each has brought us:—

(1) *Direct Measurement of Lunar Heat as compared with Solar.*—Our direct comparison indicates that we receive nearly the whole proportion of solar energy from the full moon that we should expect to get from a diffusive disk of the same angular aperture. This heat must in reality be partly diffused and partly radiated, and we do not know (from the present observations) in what proportions these two kinds enter. So far as the observation itself is reliable, we may, however, infer that our atmosphere is permeable to most of the lunar heat of either kind, but the method is unfortunately subject to such large sources of constant error, that we cannot derive great confidence from the apparent agreement of different observations or even of different observers. It may be said, however, to create a certain presumption that the earth's atmosphere is diathermanous to heat of lower wave-length than has been heretofore supposed, *and of lower wave-length than appears to reach us from the sun.*

(2) *Comparison of Moon's Heat with that of Leslie Cube.*—If we may draw any inference from this class of observations it is that the sunlit surface of the moon is not far from the freezing temperature, but not so far below as we might expect to find that of an absolutely airless planet.

(3) *Transmission of Lunar Heat by the Earth's Atmosphere.*—Our observations indicate a not materially greater co-efficient of transmission for lunar heat than for solar; and though their

limited number and the uncertainty of the correction for change of heat with phase render more certainty as to the fact desirable, we may (accepting them as probable) reason thus.

Previous observations both at Allegheny and Mount Whitney have shown that the solar rays are transmitted with greater and greater facility (except for cold bands) as the wave-length increases up to the point (near $\lambda = 3^{\mu}$) where they suddenly disappear altogether. This shows either that (1) the solar heat, which, according to the customary assumption, exists to an unlimited wave-length before absorption, has here been cut off by a suddenly absorbent action, like that of a cold band extending indefinitely below 3^{μ}, or (2) that, either through a precedent absorption of such rays in the sun's own atmosphere or their non-existence, no solar rays below 3^{μ} present themselves to our atmosphere for admission.

The first view is that which I have treated as most in accordance with received opinion. It is not, however, the only one, since the second is not to be absolutely rejected, considering our experimental ignorance of the laws of radiation from gaseous bodies for great wave-lengths. Of these two hypotheses we see that, according to the first, our atmosphere is quite opaque to all heat below 3^{μ}, and the writer's (unpublished) experiments show that heat above this point must come almost wholly from a source much above 100° C. In this view, then (unless we agree that the radiations from the lunar soil correspond to a source much above 100° C.), we conclude that sensibly none of them pass our atmosphere, but that what we receive is diffused and reflected heat coming within the range of the known solar energy spectrum, and transmitted with nearly the same facility as solar heat, or if with a little greater, because lowered in wave-length by selective reflection at the lunar surface, not by absorption and re-radiation from the lunar soil.

In the second view, for anything we have absolutely known to the contrary, our atmosphere may be permeable to radiations of any wave-length below 3^{μ}, and we could draw no certain inference, even if the lunar radiation were more distinctly different in transmissibility than it is.

As a matter of fact, with the actually limited difference in the character of its transmissibility, a difference which, as so far determined, is of the same order as that of the error of observation, we have no ground then from this present class of observation (*i.e.* Class 3) for any absolute conclusion one way or the other. But, we repeat, it seems to be a probable inference from our whole work that the earth's atmosphere is more diathermanous to heat of extremely low refrangibility than has heretofore been supposed.

(4) *Comparative Transmission of Glass for Lunar and Solar Heat.*—The evidence here, which at first seems to so directly support the view of a sensible radiation from the surface of the moon, proves, on examination, to be subject to other interpretation, for the observed effect is almost certainly due in part to a degradation of wave-length by selective reflection from the lunar soil.

We can draw no absolute conclusion, then, from this evidence, at first in appearance so promising, though we may say that it certainly indicates an increased probability for the view that radiations from the lunar soil may be transmissible by our atmosphere.

(5) *Observations during a Lunar Eclipse.*—If our own observations in this respect are imperfect, those of Lord Rosse, before cited, are, on the other hand, clear. They appear to bear but one interpretation—that all heat from the moon disappears immediately that it passes into the earth's shadow, and there is no evidence of any being retained, for any sensible time, more than if it were reflected.

It is so difficult to conceive that while the moon has been storing heat during many days of sunshine, it can part with it instantly, so that the temperature of the whole earthward surface of the planet disappears in an inappreciable interval, that most will see in this observation an argument against the existence of any such heat sensible to us at any time whatever.

(6) *Formation of a Lunar Heat Spectrum.*—The observations made here with the lunar heat spectrum are as yet incomplete. With improving experience and apparatus, we hope to make others which shall give information of a character no other means can furnish (see note, *infra*).

Conclusion.—While we have found abundant evidence of heat from the moon, every method we have tried, or that has been tried by others, for determining the character of this heat appears to us inconclusive; and, without questioning that the moon radiates heat earthward from its soil, we have not yet found any experimental means of discriminating with such certainty between this and reflected heat that it is not open to misinterpretation. Whether we do so or not in the future will probably depend on our ability to measure by some process which will inform us directly of the wave-lengths of the heat observed.

Note added February, 1885.—Since the above paragraph was written, we have succeeded in obtaining measures with rock-salt prisms and lenses in a lunar *heat spectrum*. These difficult measures must be repeated at many lunations before complete results can be obtained; but, considering their importance to the present subject, we think it best to state now in general terms, and with the reserve due to the necessity of future experiment, that they indicate two maxima in the heat curve—one corresponding within the limits of errors of observation to the solar curve maximum, the second indefinitely lower down in the spectrum, corresponding to a greater amount of heat at a lower temperature. Exactly what temperature this latter corresponds to we have no present means of knowing. We have succeeded, however, in forming a measurable heat-spectrum from the surface of a Leslie cube containing boiling water, and the maximum ordinate in the lunar heat curve appears to be below the maximum ordinate in the hot water curve. The inference from this is, of course, that the temperature of the lunar soil is, at any rate, below that of boiling water, and in an indefinite degree.

We cannot close this note without calling attention to the remarkable fact that we here seem to have radiations from the moon of lower wave-length than from the sun, which implies an apparent contradiction to the almost universally accepted belief that the sun's emanations, like those from any heated solid body, include all low wave-lengths representing temperatures inferior to those certainly emitted.

SYMBIOSIS BETWEEN FUNGI AND THE ROOTS OF FLOWERING PLANTS

A VERY remarkable phenomenon has for some time past attracted the attention of a few physiological botanists in France and Germany, and was the subject of an interesting discussion at the annual meeting of the Association of German Naturalists and Physicians at Strassburg in September last. This is no less than the discovery of the fact, which may now be considered fairly established, that a considerable number of phanerogams, especially forest trees, do not draw their nourishment directly from the soil, but through the medium of an investing layer of fungus-mycelium, to which B. Frank gives the name of Mycorhiza.

The observations which first called the attention of botanists to this interesting subject were those of F. Kamienski, on *Monotropa hypopitys*, published in the *Mém. de la Soc. Nationale des Sci. Nat. de Cherbourg*. He came to the conclusion that this plant is not, as is usually believed, a parasite, the most careful observation failing to detect any haustoria or other parasitic union with the root of any host. On the other hand, he found the root of the *Monotropa* to be completely covered by the mycelium of a fungus, which branches abundantly, and forms a pseudo-parenchymatous envelope, often two or three times the thickness of the epidermis, and especially well developed at the apex of the root. This fungus, the species of which M. Kamienski is unable to determine, is entirely superficial, not penetrating into the living cells, though occasionally forcing its way between those of the epidermis. He contends that the *Monotropa* derives its nourishment from the soil entirely through the medium of this fungus-mycelium; the only parts of the root which are in actual contact with the soil are composed of lifeless cells with no power of deriving nutriment from them. The connection of the fungus with the roots of the *Monotropa* is not one of parasitism, but of true symbiosis, each of the two organisms deriving support and nutriment from the other.

More recently similar observations on the mode of nutrition of trees belonging to the natural order Cupuliferæ have been made by Dr. B. Frank and confirmed by M. Woronin (both recorded in the *Berichte der Deutsch. Bot. Gesellschaft*). Dr. Frank finds the roots of our native oaks, beeches, hornbeams, chestnuts, and hazels, to be covered by a dense cortex of Mycorhiza, organically associated in growth with the root, and composed entirely of fungus-hyphæ, completely enveloping the whole of the root, even the growing point. The structure of this cortex is that of a sclerotium; it is composed of a dense mass of hyphæ, varying in diameter from 2 to 10 micro-millimetres, usually in several layers, other endophyllic hyphæ penetrating from them into the root between the epidermal cells, these being still slenderer than those of the envelope. By this structure, the formation by the tree of root-hairs is entirely prevented, and it is through it alone that nutriment is absorbed out of the soil. It makes its appearance first on lateral roots of the young seedling, and is constantly being replaced by fresh formations on older roots. Dr. Frank found this Mycorhiza invariably present on every root examined of trees belonging to the Cupuliferæ, also occasionally on Salicaceæ and Coniferæ, but not on woody plants belonging to other natural orders, nor on any herbaceous plant. He also regards the phenomenon as an example of symbiosis, comparable in all essential points to that of lichens, the Mycorhiza corresponding to the fungal element, the tree itself to the algal gonidia. Dr. Woronin confirms these statements in relation to Coniferæ, Salicaceæ, and some other trees, and thinks it probable that the fungus is the mycelium of a *Boletus*. He regards it, however, as truly parasitic.

In the discussion which took place at Strassburg, Dr. Frank stated that the fact of this phenomenon having been observed especially in the Cupuliferæ, was probably due to the partiality of these trees for soil rich in humus. He had observed it also in the Abietineæ among Coniferæ, the Salicaceæ, the alder and birch among Betulaceæ, and in one instance each in the lime and blackthorn. He regards it as probably much more widely diffused than previous observations had suggested. Prof. de Bary, who accepts the explanation of the phenomenon as an example of symbiosis, pointed out that a similar relationship has long been known between Orchideæ and fungus hyphæ. Observations in the same direction have also been made by Riess and Janczewski. ALFRED W. BENNETT

NORWEGIAN TOADSTOOLS

AMONG the various interesting facts regarding the history of cryptogamic plants given in the new edition of Prof. Schübeler's great work on the flora of Norway, special interest attaches to the results of his experiments on *Amanita muscaria*, one of the commonest of the Norwegian toadstools. According to Dr. Schübeler, we have in this mushroom the source whence the ancient Scandinavians derived a preparation whose intoxicating and half poisonous properties induced symptoms of frenzied excitement, similar in all respects to those exhibited by the old northern warriors when taking part in a "Berserksgang," which appears to have been very similar to the so-called "running amok." Prof. Schübeler founds his opinion on the evidence given by the Russian writers, Krascheninnikow, Erman, and others, as to the effects produced on the Kamchatkans by a decoction of the Amanita, which they used as an intoxicating drink until they were brought into closer contact with the Russians, from whom they have acquired the practice of drinking spirits. In the present day this use of the Amanita seems to be limited to the nomadic Korjakes, with whom the neighbouring Kamchatkan tribes carry on a profitable trade, giving only one or two of these mushrooms in exchange for a reindeer. According to the testimony of the Kamchatkans, the first symptom noticed after drinking this so-called "Muchamór liqueur," one of whose ingredients is said to be the juice of *Epilobium angustifolium*, is a trembling in the limbs, followed after a time by great flushing of the face and general excitement and irritability, which in the case of many is accompanied with an abnormal increase of muscular force. Thus an instance is recorded in which a man while under the influence of this stimulant ran 15 versts carrying a sack of flour on his back weighing 120 lbs., which in his ordinary condition he could barely lift. On comparing the symptoms of intoxication by muchamór recorded among the nomads of North-Eastern Asia with the accounts given by Icelandic and other northern authorities of the condition of the Berserkers in their frenzy, Dr. Schübeler finds such complete harmony that there can be no doubt of the identity of the causes to which both may be referred. We know, moreover, that while the descriptions of the Berserkergang forcibly recall the frenzy induced by the use of hachish, or opium, neither of these stimulants could have been attainable in Iceland in ancient times, nor could brandy have been used by the northmen, since it was not introduced into Norway before 1531. The employment of mead or ale by the Bersekers is equally negatived by the symptoms recorded, which the writer seems to have traced beyond a doubt to their true source. It is worthy of notice that as early as the beginning of the eleventh century the law-givers of Iceland recognised the Berserkergang as a manifestation of frenzy, for which the actors were to be held accountable, while a law was introduced in 1123 which ordained that every man who took part in these outbreaks should be banished from the island for three years, and that a similar punishment should be awarded to all who were present and who did not help to bind the Berserkers and watch over them till their excitement had passed away.

SCIENTIFIC SERIALS

Bulletin de l'Académie royale de Belgique, October 10.—Note on the crepuscular lights observed towards the end of the year 1883, by M. Hirn. A new explanation is here suggested of this phenomenon, which is attributed to a highly electric condition of the upper atmospheric layers in combination with particles of matter floating round the globe, and possibly due to the Krakatoa eruption.—On the notion of force in modern science, by M. Hirn. In this essay force is removed from the almost mystic domain it has hitherto occupied, and brought within the sphere of actual experience. The question to be determined by science is, whether gravitation, electricity, heat, &c., are to be regarded as distinct entities, or different forms of the same element absolutely distinct from what we call ponderable matter. But owing to the prevailing confusion regarding the nature of force, it is better for the present to study its various dynamic manifestations, than to attempt to reduce them to one element.—Analysis of some rocks from the "rivers of stone" in the Falkland Islands, by A. Renard. Amongst these specimens is a square prism with regular polyhedric breakage showing a granitoid texture, and altogether typical of the eruptive masses frequently interspersed amongst Palæozoic formations like those of the Falkland Islands. This fragment must be classed in the group of diabase rocks, and may serve to throw some light on the origin of the remarkable "rivers of stone" described by Darwin and Wyville Thomson.—Note on the gemmation of the channels in the planet Mars, by F. Terby. It is suggested that this curious phenomenon may be the beginning of a periodical enlargement of the channels due to causes for which no analogy can be found on the terrestrial globe.—The ancient geography of Western Asia elucidated by means of the cuneiform inscriptions, by M. Delattre. By a careful study of the itineraries and warlike expeditions described in the Assyrian and Babylonian records the author endeavours to determine the position of numerous localities unknown to the Greek and Latin writers.—The origin of the Flemish people, by L. Vanderkinden. In reply to M. Wauters' recent memoir, the author shows conclusively that the Saxon and Frisian elements are largely represented in the present populations especially of Western Flanders.

Rivista Scientifico-Industriale, October 31.—Paramagnetism and diamagnetism, by Prof. Carlo Marangoni.—On the velocity of the rays polarised round the interior of a body endowed with rotatory power, by Prof. Augusto Righi.—Experiments on the heating of boilers with petroleum, by the editor.—On the native arsenic of the Valtellona district, by D. Bizzari and G. Campani.

Rendiconti del Reale Istituto Lombardo, November 12.—Critical and exegetic essays on the sources of Roman jurisprudence, by Prof. C. Ferrini.—Theoretical treatment of the question of the ventilation of rooms, showing that in all cases the ventilating apparatus should be placed above, by Prof. R. Ferrini.—On a question of priority of discovery in bacterio-therapeutics, by E. L. Maggi.—Analytical functions of a single variant with any number of periods, by E. F. Casorati.—Meteorological observations made at the Brera Observatory, Milan, during the months of August and September.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 17.—"An Experimental Investigation into the Form of the Wave-Surface of Quartz," by James C. McConnel, B.A. Communicated by R. T. Glazebrook, M.A., F.R.S.

The paper contains an account of a number of measurements of the well-known "dark rings" of quartz. Each ring is due to one wave being retarded in the quartz behind the other by an integral number of wave-lengths, so the measurements give the directions through the plate of quartz corresponding to a series of known retardations. The relative retardation is, especially in a crystal of weak double-refracting power like quartz, mainly dependent on the distance between the two sheets of the wave-surface. Thus my observations really give the separation between the two sheets at various points, and it is in this separation that the peculiarities of quartz are most strongly marked, and the various expressions put forward by theory most widely divergent.

I found it convenient to treat separately the region near the axis, where the abnormal form of the wave-surface of quartz is most obvious. I have compared my results with nine different theories, each of which gives an expression of one of the two following forms:—

$$D^2 = P_1^2 \sin^4 \phi + D_0^2.$$
$$D^2 = P_2^2 \sin^4 \phi + D_0^2 \cos^4 \phi$$

Here D is "the number of wave-lengths by which one wave lags behind the other in air, after the light has traversed normally a plate of quartz 1 millimetre thick, the normal to whose faces makes an angle ϕ with the optic axis." D_0 is the value of D when $\phi = 0$, and is known from the rotatory power, and P_1 and P_2 are constants to which the theories assign different values. By inserting the observed values of D and ϕ, I obtained a value of P_1 and P_2 from each ring. The results from one plate about 20 millimetres thick were as follows:—

ϕ ...	4° 24′	5° 51½′	6° 51½′	7° 40½′	8° 23½′	9° 38′	11° 41′
P_1 ...	15·054	15·207	15·220	15·260	15·249	15·258	15·269
P_2 ...	15·220	15·293	15·290	15·311	15·295	15·292	15·292

Similar results were obtained from a second plate about 27 millimetres thick.

From these figures I concluded that the second expression was the correct one, and that $P_2 = 15 \cdot 30 \pm \cdot 01$. There is a considerable discrepancy in the case of the first ring, of which two possible explanations are given in the paper.

Cauchy gives $P_2 = \frac{a - b}{a^2 \lambda} = 15 \cdot 351$, where a and b are the wave-velocities perpendicular to the optic axis.

$$\text{Lommel gives } P_2 = \frac{1 - a^2}{1 - b^2} \cdot \frac{a + b}{2a} \frac{a - b}{a^2 \lambda} = 15 \cdot 178.$$

$$\text{Kettler} \quad ,, \quad P_2 = \frac{a + b}{2b} \frac{a - b}{a^2 \lambda} = 15 \cdot 486.$$

$$\text{Sarrau} \quad ,, \quad P_2 = \frac{a + b}{2a} \frac{a - b}{a^2 \lambda} = 15 \cdot 306.$$

The other five, MacCullagh, Clebsch, Lang, Boussinesq, and Voigt, have the first form of expression giving

$$P_1 = \frac{a + b}{2a} \frac{a - b}{a^2 \lambda} = 15 \cdot 306.$$

Thus Sarrau alone succeeds in explaining the observations satisfactorily.

For the larger values of ϕ I calculated on Sarrau's theory what values of $a - b$ were required to give the retardation observed in each ring, and obtained as follows:—

ϕ	15° 14′	18° 21′	23° 16½′	28° 7½′	32° 7′	35° 34′	38° 36′
$a - b$ ...	·0037916	·0037922	·0037927	·0037931	·0037939	·0037932	·0037936

The observations on the plate cut parallel to the axis gave—

ϕ	53° 58′	57° 11′	64° 45′	72° 13′	79° 53′	83° 40′	85° 37
$a - b$ ...	·0037949	·0037947	·0037945	·0037944	·0037943	·0037946	·0037944

The observations were taken in the Cavendish Laboratory, Cambridge, during the months of March and June, 1885.

For full details as to the apparatus, the plates of quartz used, the mode of observation, the precautions necessary, the temperature effects, and the calculations, reference must be made to the paper.

Edinburgh

Royal Society, December 7.—Mr. J. Murray, Ph.D., Vice-President, in the chair.—Sir W. Thomson read a paper on certain cases of motion of a liquid filling an ellipsoidal hollow; and a paper on the communication of motion from a liquid to a rigid containing shell. He showed that the motion of a liquid when rotating about the long axis of a prolate spheroid is essentially unstable, so that no great speed of rotation can be got up in the liquid in this case by making the containing shell rotate about the long axis.—Prof. Turner showed that the relative length and breadth of the sacrum may be taken as a test of development in different races of mankind. In the higher races the length exceeds the breadth.—Prof. Crum Brown read a paper on a case of interlacing surfaces. In this paper he extended the problem of the locking of threads to surfaces, pointing out that only certain surfaces can be covered over by such an interlacing system. For example, the sphere cannot be so covered, while the cylinder and anchor-ring can.—Prof. Tait communicated an elementary examination of the laws of collision of two systems of spheres, showing as clearly as possible what assumptions are necessary in obtaining average results, and how they are justified. The case in which one system of spheres gains energy from without, while the other loses to external objects, is investigated, and shows that the final average energy is not the same in the two systems, thus affording an escape from the difficulties raised by Botzmann's theorem.—In a second paper Prof. Tait defined the mean free path as the average of the free paths at any moment being described by all the particles. The definition, as usually given, is the average speed of a particle divided by the average number of collisions per particle per second. When the former definition is employed, the factor by which the mean free path is reduced in consequence of the motion of the other particles, is found to be 0·68 nearly, instead of 0·71 nearly, as found from the second definition.

Royal Physical Society, November 18.—Mr. B. N. Peach, the retiring President, delivered an address on some of the relations of Palæontology to Geology, illustrated chiefly by examples from the Scottish rocks.

December 16.—Prof. Duns, Vice-President, in the chair.—Prof. Turner, F.R.S., was elected President, and Mr. J. Harvie Brown, Prof. Duns, and Prof. Ewart were elected Vice-Presidents.—The Secretary read a paper by Mr. Robert Kidston, on the species of the genus Palæoxyris, occurring in British Carboniferous rocks.—A paper was read by Prof. Ewart, on the hatching of herring in deep water. Prof. Ewart pointed out that during recent years the herring-fishing had undergone marked changes in several respects:—(1) There had been a great increase in the "take." In 1820 only 450,000 barrels were cured, while in 1885 nearly 1,500,000 barrels were cured. (2) There had been a change in the fishing-ground; the greater number of the fish during the autumn are now caught from forty to sixty miles off shore. (3) The herring captured during the last few years off the east coast during the autumn were much smaller than those captured some ten years ago. The herring having, to a great extent, deserted the spawning-grounds in the Moray Firth, it was feared that the shoals might diminish in numbers, owing to the ova being unable to develop on the deep off-shore banks. A reference to the charts showed that the North Sea was, on the whole, very shallow—the fifty-fathom line running from fifty to thirty miles from the coast—and that there was only one small area (off Fraserburgh) where there was 100 fathoms of water. By depositing artificially-fertilised eggs in ninety-eight fathoms of water in Lochfyne, off Tarbert, it was proved that the ova develop normally, and that the only difference is one of time, the hatching being delayed owing to the lower temperature of the deep water. It was pointed out further that there was abundance of food for the fry in the off-shore waters of the Moray Firth, and that the fry, on the second day after hatching, were able to ascend at the rate of 100 fathoms in five hours.—A communication was read from Mr. A. Smith on the sucker fishes, Liparis and Lepadogaster.—Mr. Brook called attention to a peculiar method of cell-division in the early segmentation stages of fish ova. A series of vacuoles form in the plane of cleavage either at the surface or in the interior of the cell-protoplasm. By an increase in the size of these vacuoles, the two new cells become separated. Several cells may, however, remain connected together by bridge-like strands of the cell-plasma. This method of cell-division has been observed in Salmonidæ and Gadidæ, but most distinctly in the herring.—Mr. Gulland read a paper on the sense of touch in Astacus, in which he described the distribution and nature of the tactile setæ and their corresponding nerve end-organs, and discussed their origin and relations, and also the nature of certain glands in the great claw.

Mathematical Society, December 11.—Dr. R. M. Ferguson, President, in the chair.—Prof. Tait communicated a paper, which was read by Mr. William Peddie, on integrals occurring in the kinetic theory of gases. Mr. Peddie explained a method of breaking up a rectangle to form a square, and gave the first part of a paper on the theory of contours, and its application to physical science.

SYDNEY

Royal Society of New South Wales, September 2.—Prof. Liversidge, F.R.S., President, in the chair.—Mr. J. P. Josephson, A.M.I.C.E., read a paper on the history of the floods in the Hawkesbury. A number of chromogenic and pathogenic micro-organisms were exhibited and described by W. Camac Wilkinson, M.D. Lond.—An advanced copy of a work containing a series of photographs and descriptions of a case of variola occurring at the Quarantine Station was shown by Dr. J. Ashburton Thompson.—A number of microscopical slides, mounted without pressure, were shown by Mr. H. Sharp, of Adelong.

PARIS

Academy of Sciences, December 21.—M. Jurien de la Gravière, Vice-President, in the chair.—Allocution on the progress of science during the past year, by the Vice-President. —Prizes awarded during the year 1885:—Geometry: Bordin prize to M. P. Appell (2000 fr.) and M. Otto Ohnesorge (1000 fr.); Francœur prize, M. Emile Barbier. Mechanics: Extraordinary prize of 6000 fr. to M. Hélie (2000 fr.) and MM. Hugoniot, Doneaud du Plan, Hatt, and Lucy (1000 fr. each); Poncelet prize to M. Henri Poincaré; Montyon to M. Amsler-Laffon; Plumey to MM. Bienaymé and Daymard; Dalmont to M. Lucas; Fourneyron to M. Colladon. Astronomy: Lalande prize to M. Thollon; Valz to M. Spörer; Bordin to M. Edlund; Lacaze to M. Gernez. Statistics: Two prizes to MM. de Pietra Santa and Keller. Chemistry: Jecker prize to MM. Prunier and Silva (4000 fr. each) and M. G. Rousseau (2000 fr.). Geology: Delesse prize to M. Lapparent. Botany: Barbier prize to MM. Dubois, Heckel, and Schlagdenhauffen; Desmazières to M. Leclerc du Sablon; Montagne to M. Patouillard. Anatomy and Zoology: Grand prize of the Physical Sciences to M. Joannès Chatin; Da Gama Machado to M. Girod. Medicine and Surgery: Montyon to MM. Charpentier, Farabeuf, Regnauld, and Villejean (2500 fr. each), Bréant to M. Mahé; Godard to M. Desnos; Lallemand to M. Grasset. Physiology: Lacaze prize to M. Duclaux; Montyon to M. Remy. Physical Geography: Gay prize to Capt. Defforges. General prizes: Montyon (industries injurious to the health) to MM. Girard and Chamberland (2500 fr. each); Cuvier to M. Van Beneden; Trémont to MM. Bourbouze and Sidot (1000 fr. each); Gegner to M. Valson; Petit d'Ormoy (Mathematical Sciences) to M Halphen; Petit d'Ormoy (Natural Sciences) to M. Sappey; Laplace to M. E. G. A. Coste.—Prizes proposed for the year 1886:—Geometry: A study of the surfaces admitting all the symmetrical planes of one of the regular polyhedrons (3000 fr.); Francœur prize, The work most conducive to the progress of the pure and applied mathematical sciences (1000 fr.). Mechanics: Extraordinary prize of 6000 fr. for any work tending most to increase the efficiency of the French naval forces; Montyon (700 fr.), Invention or improvement of instruments useful to the progress of agriculture, of the mechanical arts or sciences; Plumey (2500 fr.), Improvement of steam-engines, or any other invention contributing most to the progress of steam navigation; Dalmont (3000 fr.), The best work by any of the Ingénieurs des Ponts et Chaussées in connection with any section of the Academy. Astronomy: Laland prize (gold medal worth 540 fr.), for the most interesting observation on work most conducive to the progress of astronomy; Damoiseau (10,000 fr.), Best work on the theory of Jupiter's satellites, discussing the observations and deducing the constants contained in it, especially that which furnishes a direct determination of the velocity of light; Valz (460 fr.), for the most interesting astronomical observation made during the course of the year. Physics: Grand prize of the Mathematical Sciences (3000 fr.), for any important improvement in the theory of the application of electricity to the transmission of force. Statistics: A prize of 500 fr. for the best work on the statistics of France. Chemistry: Jecker prize (5000 fr.), for the work most conducive to the progress of organic chemistry. Geology: Vaillant prize, on the influence exercised on earthquakes by the geological constitution of a country by the action of water or of any other physical causes. Botany: Barbier prize (2000 fr.), for any valuable discovery in the medical and botanical sciences bearing on the healing art; Desmazières (1600 fr.), for the best or most useful work, by a Frenchman or a foreigner, on the cryptogamic plants. Anatomy and Zoology: Savigny prize (975 fr.), for the best work on the invertebrate animals of Syria and Egypt. Medicine and Surgery: Bréant prize (100,000 fr.), for an efficacious remedy against cholera,—discovery of the true causes of Asiatic cholera, with a view to its suppression, or for the discovery of any certain prophylactic against cholera. Physiology: Montyon prize (750 fr.), for the best work on experimental physiology. Physical Geography: Gay prize (2500 fr.), researches on the differences of sea-level in the vicinity of the continents due to local attraction or relief of the land, with examples illustrating the reality of this phenomenon. General prizes: Montyon prize, for any discovery useful to the healing art or tending to render unhealthy industries less injurious; Delalande-Guérineau prize (1000 fr.), for any French traveller or any naturalist who shall have rendered the greatest service to France or to science; Jerome Ponti prize (3500 fr.), for any work judged most useful for the advancement of science. Competitors for these prizes are reminded that all papers must be sent in before June 1, 1886, and that no documents will be returned by the Academy. Copies, however, may be procured through the Secretary.

BERLIN

Physiological Society, Nov. 13.—Prof. Munk reported on experiments carried out by Dr. Ziehen in his laboratory, with a view to deciding the question whether epileptic convulsions, artificially induced by electric stimulation of the brain, proceeded from the cerebral cortex or from centres of deeper situation. By weak electric stimulation of a motory region of the cortex continued for a longer time, or by a stronger stimulation for a shorter time, it was found, after removing the electrode, that convulsions originated in the muscles corresponding with the stimulated region, thence propagating themselves gradually over the whole body. After the stimulation of one region of the cortex, a cause of convulsion was accordingly left in it, gradually overtaking the other centres of the groups of muscles. The question was, whether this propagation of the cause of convulsion took place in the cortex, where, map-like, were situated, adjacent to each other, the regions for the muscles of the eyes, ears, face, anterior and posterior extremities—or whether the propagation got transferred directly to the deeper centres of the muscle sections, gradually taking possession of them. This problem Prof. Luciani endeavoured to solve by exciding a centre of muscle groups out of the cortex, such as that of the anterior extremity, and then causing the convulsive fit artificially. The result he found was that all the muscles gradually fell into a state of convulsion, with the exception of those of the anterior extremity. This experiment, apparently settling the question, had been confirmed by some physiologists, but not by others, so that it became necessary to institute experiments afresh. Dr. Ziehen had now made the observation that under sufficiently long application of weak stimulations the convulsion ensuing and gradually spreading over the whole body was a clonical one, and that under moderately strong stimulation tetanic allied themselves to the clonical spasms, while under very strong stimulations the tetanic contractions preponderated. When, in accordance with Prof. Luciani's procedure, he had excided a region of the cortex and then applied stimulation by weak currents, the clonical spasms showed themselves in all groups of muscles, with the exception of those corresponding with the excided portion of the cortex. When, on the other hand, he applied stimulation by strong currents, he observed the tetanic convulsions assert themselves at those parts likewise of the body, the cortex region of which had been excided, even if weaker at this latter part than in the other muscles. From this result the speaker inferred that the spasmodic stimulation, in the case of clonical contractions, propagated itself in the cortex, and that in the case of tetanic contractions the spasmodic stimulation propagated itself in the deeper parts of the brain. In support of this inference Prof. Munk adduced the succession of the groups of muscles overtaken by spasm. The position of the motory centres in the cortex was precisely known, whereas the local distribution of the deeper centres was unknown. Now, the clonical spasms proceeding from the spot of excitation followed each other precisely in that succession in which the centres of the cortex arranged themselves conterminously, while the succession of tetanic spasms formed a different and irregular series. Further evidence in support of the conclusions just stated was afforded by the following experiment. A region of the cortex having been stimulated by weak currents sufficiently long to induce clonical spasms in the muscles corresponding therewith, and in the muscles belonging to the adjacent region, the part of the cortex first affected was excided. The consequence was that the spasm now propagated itself no further, but ceased entirely. In the case, however, of tetanic spasms, the excision of the stimulated part of the brain had no effect. In refutation of the objection that might possibly be urged, namely, that in the main experiment the excision of a determinate part of the cortex was followed by an exemption from spasms in the group of muscles belonging to that part, for the reason that the excision caused a stimulation which induced a counteracting excitation in the muscles in question, Prof. Munk adduced the fact that he had observed the same result in animals that had been tested in this manner eight months after the excision, when there could no longer be any question as to a stimulation in the part where the excision had been made.—Prof. H. Munk next communicated the observations he had made on pigeons from which he had cut out the corpora striata. The conditions in respect of the corpora striata were very different in birds from those obtaining in Mammalia, seeing that in the brain of birds the corpora striata composed the main mass, whereas in the brain of the Mammalia they retired considerably into the background. If these were now removed on both sides from pigeons, the pigeons yet acted altogether normally, and the functions of all their senses continued unimpaired. With careful attention for a length of time three deviations from the normal state could yet, however, be remarked. The back of the pigeons was curved strongly convex; they never perched either by day or by night; and could never snap up a pea, however much exactness they showed in pecking at any pea laid before them, seeing that in pecking they never opened the beak. The animals had therefore to be fed artificially. In consequence of these observations Prof. Munk conjectured that the corpora striata were the seat for the combination of movements. —Following up this subject Dr. Lehmann stated some provisional results which, in conjunction with Dr. Baginski, he had found in rabbits, in which the corpora striata had been injured. The phenomena resulting under like conditions in pigeons had not been observed. The investigation in this field was still being continued.—Prof. Liebreich gave a short sketch of a series of investigations which had engaged him for some years, and had led to the introduction of a new substance into the pharmacopœia. He premised that the denomination "fats" would have to cover more than it had hitherto done, and not merely such substances as were capable of decomposition in fatty acids and glycerine. All substances, on the contrary, would have to be conceived of as neutral fats, which contained sebacic acids, no matter with what organic base these were combined. Such a neutral fat was discovered by Herr E. Schulze, in 1869, in the yolk of the fleece of sheep, and which consisted of a sebacic acid and cholesterine. This cholesterine fat of sheep's wool, or "lanoline," had been studied by Prof. Liebreich, as to the method of obtaining it on account of its excellent qualities in the way of a salve constituent; it was now being extracted from woollen hairs by means of a centrifugal machine and had become an article of trade. Prof. Liebreich had next investigated the origin of this cholesterine fat, and, with the help of the uncommonly sensitive cholestol reaction of Prof. Liebermann, had come to the conclusion that the cholesterine fat contained in the yolk of sheep was derived neither from the sudorific glands nor from the sebaceous glands, nor from the sebaceous texture of the under-skin, but was seated exclusively in the hairs and in the epidermis cells. This fact led, on the one hand, to the production of the substance as a kind of manufacture, while on the other hand it induced a very extensive series of experiments respecting the distribution of cholesterine fat in the animal kingdom. The speaker found it in the epidermis, the hairs and nails of men, in the hairs of all Mammalia he had examined, in the hoofs of horses, in the paws of swine, in the horns of cattle, in the prickles of the hedgehog, in the feathers of fowls, geese, and a large number of other birds, in the plated sheaths of the tortoise; in short, in all horned textures which, with long and toilsome labour, he had examined. The speaker had, in addition, found the cholesterine fat in the kidneys and the liver of Mammalia; yet it was not beyond question that in these organs the cholesterine fat did not proceed from the blood, in which it was always present in small quantities. It might be conjectured that it would likewise be found in the intestinal canal, and generally wherever epithelial cells occurred. The constant presence in all epithelial formations of a particular fat, which was there formed in the keratine cells, rendered it highly probable that the hairs of the Mammalia and the feathers of birds owed their elasticity and pliancy not, or at all events not exclusively, to the secretion of the sebaceous or caudal glands, but to the cholesterine fat generated in the horn cells themselves. The quality possessed by cholesterine fat of not oxidising, or oxidising only under very rare conditions, rendered it, as was very readily conceivable, most peculiarly adapted for lubricating the skin and feathers. Beyond the property of not becoming rancid, lanoline possessed a whole series of other advantages distinguishing it quite peculiarly as a salve constituent. It absorbed, for example, 100 per cent. of water, and by so doing became a soft substance easy to the touch, penetrating the skin with altogether extraordinary facility, and after but a short rubbing into the cutis, disappeared from view. Prof. Liebreich had already prepared into salves a great number of medicamental stuffs by means of "lanoline," and had made experiments with them which yielded entirely satisfactory results. Lanoline, dark brown in a dry state, grew pale like wax in light, and showed other qualities besides assigning it a place between the ordinary glycerine fats and the wax kind of fats.

STOCKHOLM

Academy of Sciences, November 11.—The following papers were read and accepted for publication in the Society's *Journal*:—Lois de l'équilibre chimique dans l'état dilué, gazeux, ou dissous, by Herr J. H. van't Hoff.—Recherches sur les réactions chimiques dans le champ du microscope, by Prof. E. G. Fatigoti, of Madrid.—Some remarks and experiments on filtration, with reference to its bearing upon the process of transudation in the animal body, by Drs. R. Tigerstedt and G. Santesson.—*Hæmatodeptes terebellidis*, une nouvelle Annélide parasitique de la famille des Euniciens, by Prof. A. Wirén.—On the constitution of some derivatives of naphthaline, by Dr. A. G. Ekstrand.—On combinations of phenyl-textra-zol, by Herr J. A. Bladin.—On the integration of the differential equations of the intermediate orbits, by M. C. V. L. Charlier.

THE RACES OF BRITAIN

The Races of Britain; a Contribution to the Anthropology of Western Europe. By John Beddoe, M.D., F.R.S., &c. (London: Trübner; Bristol: Arrowsmith. 1885.)

BELIEVING that after thirty years of labour his opportunities for observation are not likely to add much to his store of facts, or materially alter their significance in his own eyes, Dr. Beddoe has brought together his numerous contributions to the ethnology of the British Isles, and, with the addition of much new matter, has arrayed them before us in such a manner as to show his own conclusions, and to form "some small part of a solid platform" whereon future anthropologists, with antiquaries and philologists, may ultimately build a more complete and certain structure.

Dr. Beddoe's mode of procedure is to make extensive observations on the physical characters of the present inhabitants of our islands, and on those of the adjoining parts of the Continent which are the reputed cradles of the various elements of our race, and to compare the results with the records of history as far as they are available. The physical characters to which he attaches most importance are colour of hair and eyes, head-form, and stature, and of these he has collected a very large number of observations on a systematic plan, and hence the "numerical method" of studying anthropology which he first inaugurated in 1853, and which has since been largely followed by continental observers. Dr. Beddoe attaches most importance to colour, because he believes that "the colour of the hair is so nearly permanent in races of men as to be fairly trustworthy evidence in matters of ethnical descent; and that nearly as much may be said for the colour of the eyes." With regard to head-form he complains of the great dearth of measurements of modern British skulls, the skulls in our museums being chiefly those of criminals, lunatics, and paupers, and therefore of little value; and he finds from personal experience that the accurate measurements of living heads are alike difficult to make and to obtain. He supplies tables, however, of a considerable number of measurements of heads obtained by himself or his friends in different parts of the country. The statistics of stature and weight collected by Dr. Beddoe have been dealt with in a separate essay, and as they were incorporated with others of a similar kind collected by the Anthropometric Committee of the British Association, and published in their final report for 1883, they are, therefore, not republished in his present volume.

It is to his extensive observations on the colour of the hair and eyes that Dr. Beddoe chiefly trusts for his analysis of the racial distribution of our existing population, and for the purpose of more convenient and definite comparison he adopts a formula which serves as an "index of nigrescence." Having classified the colour of the hair as red (R), fair (F), brown (B), dark (D), and black (N), "the gross index," he says, "is gotten by subtracting the number of red and fair-haired persons from that of the dark-haired, together with twice the black-haired. I double the black, in order to give its proper value to the greater tendency to melanosity shown thereby; while brown (chestnut) is regarded as neuter, though most persons placed in Class B are fair-skinned, and approach more nearly in aspect to the xanthous than the melanous variety:—

$$D + 2N - R - F = \text{index.}$$

From the gross index, the net, or percentage index, is of course easily obtained."

Dr. Beddoe is quite alive to the want of uniformity in the manner of observing, to the different significance of the terms employed for the colours of hair and eyes, and to peculiarities in observers themselves, but as the data he makes use of were collected by himself, the personal equation of the observer and the terms employed are constant. He does not explain the principle on which his classification of colour of hair and eyes, is based, and it would seem to be the result of combinations which his very extensive observations have suggested as the most constant and consistent with each other and with other physical characters, as he claims for it a closer appositeness for defining racial distinctions than other schemes. It differs from the plans of Virchow, Vanderkindere, and Kollmann, and other continental anthropologists, and from that of the Anthropometric Committee, which is based on the simple anatomical arrangement of pigment in and on the surface of the iris, hair colour being deemed of secondary importance both from the difficulty of diagnosis and its greater changeableness with age.

Dr. Beddoe's account, extending over eleven chapters, of the prehistoric races, and the various conquests of the Romans, Anglo-Saxons, Danes, and Normans, and the fresh blood which they introduced into the country, is very fully and impartially rendered. The natives of South Britain at the time of the Roman conquest, according to Dr. Beddoe, "consisted mainly of several strata, unequally distributed, of Celtic-speaking people, who in race and physical type, however, partook more of the tall blond stock of Northern Europe than of the thick-set, broad-headed, dark stock which Broca has called Celts. . . . Some of these layers were Gaelic in speech, some Cymric; they were both superposed on a foundation principally composed of the long-headed dark races of the Mediterranean stock, possibly mingled with fragments of still more ancient races, Mongoliform or Allophylian. This foundation-layer was still very strong and coherent in Ireland and the north of Scotland, where the subsequent deposits were thinner, and in some parts partially or wholly absent . . . no Germans, recognisable as such by speech as well as by person, had as yet entered Britain."

Dr. Beddoe appears to hold a middle place between the writers who believe, on the one hand, in the extermination of the native races by the Anglo-Saxons, and on the other in their extensive survival in all parts of the country; while he attaches more importance to the new blood introduced by the Danes and Normans than is commonly admitted.

The portion of the work devoted to an analysis of the racial elements of the present inhabitants of the British Isles and adjoining countries of Western Europe consists of a very large number of tables showing the distribution of the colour of hair and eyes according to the "index of nigrescence," and to a less extent to the head-forms, from the author's personal observations; and of second series of colour of hair and eyes of military deserters illustrated by maps constructed on the plan of the Anthropometric Committee. There are also tables showing the relation between complexion and disease collected at the Bristol Infirmary; and numerous illustrations are given showing the physiognomy of males and females which the author believes to be typical of the various racial elements at present surviving among us.

Of the conclusions which Dr. Beddoe draws from all these observations it is impossible to give a summary here. He examines the whole country, district by district and county by county, from the Shetlands to Cornwall, and the reader must consult the work itself to see how far the author has succeeded in the task he has set himself, and to what extent he has prepared a solid platform for his successors in the same field of inquiry. It is most probable that Dr. Beddoe's conclusions, based as they are on a minute acquaintance with the history of the conquests and settlements of the country, and on a wide personal survey of the population in most stationary situations, will be accepted by anthropologists as the best results and the nearest approach to the truth which is attainable at the present day. On the other hand it is doubtful whether Dr. Beddoe's confidence in colour as a permanent racial character will bear the test of future inquiry, and whether his method will be accepted as sufficient when the questions of prepotency of stock, relative viability of dark and blond persons, and the influence of sexual selection have been more completely investigated. The Jews of Europe are isolated and preserved as a separate race by the sterility or low fertility of their mixed marriages, and the question of hybridism in the human race has received little attention from anthropologists. The function of reproduction is the most highly specialised and the most easily disturbed, and it is probable that the dying out of races is due more to this cause than to the "vices of civilisation" to which they are commonly attributed. American statistics show that the blond type is more subject to all the diseases, except one (chronic rheumatism), which disqualify men for military service, and this must obviously place blonds at a great disadvantage in the battle of life, while the popular saying, "a pair of black eyes is the delight of a pair of blue ones," shows that sexual selection does not allow them to escape from it. It is more than probable, therefore, from all these considerations, that the darker portion of our population is gaining on the blond, and this surmise is borne out by Dr. Beddoe's remark that the proportion of English and Scotch blood in Ireland is probably not less than a third, and that the Gaelic and Iberian races of the west, mostly dark-haired, are tending to swamp the blond Teutonic of England by a reflex migration—a fact not without significance to others than anthropologists at the present time.

The "Races of Britain" gives a very imperfect idea to those who are unacquainted with such inquiries, of the labour, time, and thought expended on its production, but anthropologists who know how to estimate such work at its full value will welcome it with great satisfaction as the most exhaustive account of the ethnology of our country which has appeared in recent years.

CHARLES ROBERTS

OUR BOOK SHELF

Journal of the Royal Agricultural Society. Vol. 21, Part II., Series II. (London: John Murray, 1885.)

THE second part of the current number of this *Journal* opens with the second instalment of Mr. Fream's report upon Canadian agriculture. The climate, soil, and products of Eastern Canada, comprising the better-known States of Ontario, Quebec, and the maritime provinces, are chiefly dealt with, whereas, in the first report, prairie farming, and the almost untrodden regions of the north-west were particularly dealt with. The principal object of the report is to show the capabilities and rapid progress of Canada, and this is achieved by numerous statistics as to production and exports. In these provinces the first fertility of the soil has been in a great degree exhausted, and as a consequence mixed farming with the maintenance of live stock, and the use of improved processes, is taking the place of consecutive corn-growing. The growth of the dairy industry is a remarkable fact, and in the management of their cows and the manipulation of the products of the dairy, more attention is apparently paid to the teachings of science than is usual in the mother country. The exports of cheese have increased from 6,000,000 pounds per annum in 1870, to 76,000,000 pounds in 1884. The butter trade has long been stationary, owing to the uncertain demand for Canadian butter. The Canadian cattle trade has also increased by leaps and bounds from a gross number of 6940 head in 1877, to 61,843 in 1884. The report is full of details of personal experience gained from many settlers in all parts of Old Canada. Names and addresses of the principal farmers, dairymen, and stock-breeders, are given with great frequency, and confer a special value on the report as a guide to intending settlers.

A large portion of the *Journal* is occupied with official reports of the Preston meeting of the Society (1885), including the report upon the prize farms in Lancashire. These last reports are less interesting than usual to practical men, as the Lancashire farmers are exceptionally placed, and conduct their business upon suburban principles of management. The sale of farm produce directly to the town consumer and the carrying back of town manure is the marked feature. Rents appear to range particularly high for the present depressed state of trade and agriculture, and are generally from fifty to sixty shillings per acre.

The customary reports of the Steward upon live stock and implements, and short memoirs of the late Sir B. T. B. Gibbs and Sir Watkin W. Wynn, close this section. A summary of the Commission's Report on Technical Education, 1884, and a reprint from the Report of the Pennsylvania State Board of Agriculture, 1883, occupy some fifty pages, the latter reviving M. Guénon's curious theory with regard to indications of milking properties in the peculiar distribution of hair on the buttocks, known as the "escutcheon."

Among original articles indicating research, those of Miss E. Ormerod on the ox-warble and the warble maggot, of Prof. Robertson upon rickets in sheep, and of Mr. Clement Stephenson upon abortion in cows may be mentioned. Lastly, the number contains a contribution from Rothamsted upon the valuation of unexhausted manures, in which the results of past experiments are brought to bear upon the claims of outgoing tenants for compensation under recent Acts of Parliament.

From Paris to Pekin over Siberian Snows. By Victor Meignan. Edited, from the French, by William Conn. (London: W. Swan Sonnenschein and Co., 1885.)

THE mode in which this volume has been produced is rather curious. In 1873 M. Meignan, who had already travelled in the regions around the Levant for pleasure, took it into his head that, by way of contrast to these lands of the sun, he would like to see a land where snow and ice were predominant, and accordingly he undertook to travel from France to China through Siberia. He appears to have had no object in the journey but the pleasure of motion and of seeing new and strange objects. It was undertaken in the winter, and the traveller naturally saw, and was interested in, Moscow, Nijni-Novgorod, the Urals, and so travelled through Siberia by Omsk to Irkutsk. After a short stay in the latter place he pursued his journey through Kiachta, Urga, and Kalgan to Pekin. Many travellers have done the journey before and since; it is a long and tedious one, and perhaps that is as much as can be said for it. Mr. Conn talks of crossing "the trackless Desert of Gobi" on the way, but this is an abuse of language. The only part of the Gobi passed is that between Urga and Kalgan, two considerable trading cities, between which caravans, couriers, and travellers go daily along a high road which is a very good one as roads go in Asia. But M. Meignan, having done the journey, and being of a lively and amusing turn, wrote an account of it some time after his arrival in France. This account of a journey in 1873 Mr. Conn has "edited" in 1885; he has, he says, produced a modified version rather than a translation, the modifications consisting in correcting the slipshod style of the original, in producing "a more just co-ordination of parts and subordination of minor details," and also in expanding the original here and there. The volume, notwithstanding this dual authorship, is pleasant reading, much as a tolerably written account of a journey in Wales or Scotland would be pleasant. There are not a few errors, especially as the traveller gets farther east, but these cannot seriously interfere with such enjoyment as may be derived from a perusal of the volume. As Mr. Conn has a taste for this species of literary work—having published another volume, an adaptation or translation of a Japanese tale by a French writer, during the year—we would suggest to him that he should select his originals more carefully. A sterling popular work in French or German might very easily prove a sterling popular work in English; there can be little real use in reproducing trumpery French books in English, except to add to the already enormous mass of similar indigenous literature in England.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Iridescent Clouds

ON December 29 just passed, at 3.40 p.m., or shortly after sunset, and during the late frosty storm, there was a brilliant repetition of the iridescent clouds concerning which I wrote to NATURE about a year ago. The tendency of many of these little clouds, or cloudlets, to rectilinear rhomboidal forms was remarkable; also their confinement in point of colour to blue, violet, rose-pink, and green—eschewing yellow, orange, and vermilion reds: while the sunset sky below them was, on the contrary, a gorgeous panorama of all those yellow-*cum*-red partaking colours.

That so good an example of these iridescent cloudlets is not very frequent may be concluded from the number of letters which this occasion has already produced in the *Scotsman* newspaper here, and of which I send you six.

C. PIAZZI-SMYTH

15, Royal Terrace, Edinburgh, January 1

Peculiar Meteorological Phenomenon.—A somewhat rare phenomenon was observed at Burntisland, Falkirk, Laurencekirk, and many other parts of Scotland yesterday. A large number of miniature rainbows presented themselves in the sky, with the red, orange, yellow, and green colours distinctly discernible. They were not larger than the ordinary sun as it appears to the naked eye, and, after remaining visible for a considerable time, gradually faded away.

Fraserburgh, December 28, 1885

SIR,—To-day, at 3 p.m., a heavy snowstorm from the west-north-west was just clearing off here. Along the horizon, from west to south-west, lay a heavy bank of storm-cloud, hiding the sun. Above this, in same general direction, was a belt of clear sky. Above that, as the rack drifted off to south-east, there was disclosed a belt of light cirro-stratus cloud, in same general direction, about 30° from the sun, and evidently at very great height, for it kept the same general position nearly an hour, though with considerable variation of form. When first visible it was fringed on the side next the sun with bands of the most vivid and delicate prismatic colours—in series, blue end outside and red (prolonged into a splendid band of violet) inside. Detached portions, however, had the bands all round. The appearance continued in its first splendour only a few minutes, but less vividly for some time longer. It would be interesting to know whether the same appearance was seen at other places; and, if so, at what hour, and at what angle from the sun?

W. MACGILL, B.A.

Edinburgh, December 29, 1885

SIR,—I write to ask if any of your readers can give an explanation of a remarkable phenomenon which was visible in the western sky this afternoon. Just after sunset a few thin patches of cirrus clouds not far west of the zenith assumed a rich opal hue, while in others all the colours of the spectrum were beautifully displayed. The appearance of one of these clouds was exactly similar, in fact, to a completed, though, of course, miniature rainbow. This phenomenon continued for some time after the sun had set, and at times the colours could be seen to change rapidly. A cold frosty wind from the north-west was blowing at the time. C. M.

Maxton, December 30, 1885

SIR,—With reference to the two letters on this subject in to-day's *Scotsman*, it may interest you to know that the cloud phenomenon in question was witnessed here twice yesterday. About 8 a.m. the sky was perfectly clear, and the crescent moon was shining in the south-west. As the radiance of the sun, as yet beneath the horizon, began to appear, several detached clouds, of a semi-transparent, filmy nature, suddenly came into view in the south-eastern sky, which had, a moment or two before, been without a single speck to dim it. These clouds, at first of an indefinable colour, quickly heightened in tone, and the prismatic colours became visible with gorgeous distinctness, increasing in intensity as the sun neared the horizon. The top band was of a peculiar blue, obviously different from the sky field. Beneath was a wave of rich rose-pink, next a cloudy-orange, with light streaks or "watermarks," then a rich mass of deep violet, fading lower into white. There were three large clouds, the upper and lower lines of which were quite level and perfectly parallel, though the edges to the east and west were sharp and ruggedly cut. In the case of one of these clouds the denser part was apparently rhomboidal, but on its eastern side, and connected with it, was an opalescent vapour filling up the space between what I may term the base and the hypothenuse of an angle of about 15°. The base of this incomplete triangle was equal in length to the base of the incomplete rhomboid. The lines were most clearly defined. There were a number of minute cloudlets, some the merest specks, but all showing the same colours that I have mentioned. They did not remain very long in this distinct state. As the sun rose above the horizon they became beautifully opalescent, and their forms began to change in a wavy manner, and in a short time vanished as in ether from that part of the sky. The sun was now at a slight altitude, and when I turned round I saw to my astonishment similar clouds, though the colours were less distinct, in the north-west, where a few minutes previously none were to be seen. These did not last long, though during their short appearance their outlines were very distinct, there at the time being a heavy haze of reddish gray, changing to dusky carmine above the northern horizon. At this time a west wind was blowing with considerable force, but these clouds appeared to be high above the wind, as they were certainly not influenced by it. In mid-air there seemed to be a counter current, as light cirrus cloud-streaks drifted slowly across the zenith from the east. About 4 p.m. the same phenomenon occurred in the west and north-west, the clouds, if anything, being more beautiful than in the morning. They remained for a time after the sun had set. At 5 p.m. the thermometer registered 12° of frost. I trust I have succeeded in a partial way to convey some idea of sky effects so inexpressibly beautiful as to baffle description. I was informed last night that the previous Monday afternoon, as a party of noblemen and gentlemen were returning to Tynehead Station from a day's shooting on the Humbie Estate, in East Lothian, and while a terrific storm of wind and sleet prevailed, there was a sudden rift, through which the party saw a number of clouds of a similar nature to those I have attempted to describe. JOHN THOMSON

Maxton, Wednesday Afternoon

At 3 p.m. we have had a steady fall of snow for four hours.
JOHN THOMSON

Wick, December 30, 1885

SIR,—Your correspondent "C. M." in to-day's paper exactly describes the phenomenon as it was seen here. The cirrus clouds were probably floating at a very high elevation in a stratum of air much below the freezing-point, and their structure thus having undergone some change, the sunlight became decomposed, causing the prismatic display. This theory may or may not be correct, but the end of the cirrus band farthest from the sun lost the colours first, and the end nearest the sun was the last on which a vestige remained after the sun had set. NEMO

Sunderland, December 30, 1885

SIR,—I have just read in to-day's *Scotsman* the letters of your correspondents in Fraserburgh and Edinburgh concerning the atmospheric or cloud phenomena of Monday, 28th. The appearance of the heavens here from 3.30 p.m. was most striking. The sun set in a rich water-glow, and the sky in the west being very free from obscuration, we could notice how the glow deepened as it ascended, until from 20° to 50° it presented a dark crimson or purple. Just above Venus—which was like a silver ball—there were seen some cirro-stratus clouds—bright and luminous—just like illuminations on a dark ground. They were stationary, and retained their shape for a very long time. At their western extremities were seen all the prismatic colours, as if they were encircled with rainbows. These colours were very distinct for half an hour, and then gradually disappeared; but still the clouds remained, and were seen at 5.20—almost in their original position—as bright electric clouds. I have observed the heavens for thirty years, but never saw so beautiful a cloud-display. I think the explanation is that the various strata of the atmosphere retain certain rays of light longer than usual when the sun's light falls at the oblique angle it has in December. These clouds evidently rested in a part of the atmosphere not affected by the disturbances nearer the earth.

D. PATTERSON, M.A.

ON going out at 4.12 p.m. to-day, I saw several remarkable clouds in the west part of the sky, somewhat similar to those described by Prof. Piazzi Smyth and several other correspondents in NATURE, vol. xxxi. pp. 148, 192, 264, 315, 338, 360. These clouds were collected in three groups, about south-west, west, and north-west respectively. Some of them were streaked, and the streaks and longer axes of all the clouds were directed approximately towards the spot where the sun had recently set. At the time when I first saw them, only one of these clouds showed prismatic colours, but I am informed by a friend that a little earlier, about 4 p.m., this was the case with several. As the other two sets showed colours and changes exhibited later on by those in the south-west, I propose to describe the latter alone.

At 4.12 this group consisted of two large clouds and several smaller ones, just above the planet Venus, the centre of the group being at an altitude of about 30°. The uppermost cloud was about 20° in length and 5° in breadth. Its longer axis was directed towards, but slightly above, the point in the horizon where the sun had just set. The west end of the cloud was rounded, almost semicircular, and hazy near the edge. Then followed two or three fringes, also nearly semicircular, showing rather bright prismatic colours, the blue side of each fringe being towards the sun. The coloured fringes occupied about a third of the cloud; the rest of it was bright, with a slightly greenish tinge, as were also the other clouds of this group. The east end was drawn out in striæ parallel to the longer axis of the cloud. Soon after my first seeing them, the prismatic colours began to fade, and by 4.20 were no longer distinguishable, but the clouds themselves were still bright and noticeable. At 4.25 the cloud that had the prismatic fringes became very faint and had now a slight rose-coloured tinge; the others had the same tinge of colour, but remained bright. By this time the striæ at the east end were drawn out in the direction of the length of the cloud, but became gradually fainter, and by 4.27 had disappeared; so that the cloud was now reduced to about half its original length, the remaining part having at the same time become broader, brighter, and of a deeper rose-colour. This colour, however, soon began to fade, and by 4.34 was nearly gone, though there was no apparent diminution of brightness. At 4.41 they were bright and of a grayish-white, almost steel-gray, colour, and continued so for some time. During all the time I watched them (about three-quarters of an hour) this group as a whole was nearly stationary, though the clouds themselves changed considerably in form and slightly in their relative positions. The sky was almost clear, but near the horizon there were some dark, heavy clouds, and at one time (4.25) several of these, driven by a strong wind, passed rapidly below the group above described, partly covering the lowermost. On going out again at 6.20 to watch them, I found that they had all disappeared. I may add that yesterday evening, soon after sunset, the western sky was covered with a rosy flush, reminding one slightly of the wonderful sunsets of two years ago. CHARLES DAVISON

Sunderland, December 28, 1885

YESTERDAY morning (December 29), from about 8.30 to 9 o'clock, a number of very brilliantly-coloured clouds were observed here by myself and others. The weather was cold and frosty, and the sky at the time was clear with the exception of a thick haze round the horizon; a few clouds were thinly distributed over the sky, and these were more or less coloured. The clouds in the south-east had colours rivalling those of the rainbow in intensity. The colours were also distributed in bands, though not in the same order as those of the rainbow. The clouds in the opposite quarter of the sky were smaller, and though unusually bright as regards luminosity the colours were paler than on the other side of the sky. Each cloud also had one uniform tint, a pale green or blue or pink. The more brilliant clouds while fading assumed an appearance similar to these others, some of the bands broadening out, while others disappeared. I saw a beautiful iridescent cloud here at the same hour one morning last December. At that time the phenomenon was generally observed throughout the country, as is evident from the letters which appeared in NATURE (vol. xxxi. pp. 148, 192, 264, &c.). JOHN STEVENSON

Broxburn, December 30, 1885

The Recent Star-Shower

MR. DENNING's letter of December 12 makes me see that I did not put the point which was in my own mind with sufficient clearness in my letters of December 7 and 8.

It was not to coincidences of star-showers with displays of auroræ as to whose true auroral nature there appeared to be no question, that I wished to draw attention, but to the fact that, among the instances to which I referred, of the coincidence of such showers with *aurora-like phenomena*, there were two occasions, and those two occurrences of the same shower, on which there was a notable absence of any magnetic disturbances. The coincidence of such disturbances with auroral displays is, I suppose, so thoroughly established that the notable absence of them on these occasions may fairly be taken to suggest a possibility that the phenomena were not truly auroral. If so, their coincidence with the star-shower becomes more noteworthy.

Rugby, January 5 J. B. HASLAM

A SPLENDID shower of meteors occurred on the night of November 27, 1885. Seen from Ava, near Mandalay, at 10 p.m. mean time of place, the point of emergence was near the zenith, and the shower radiated to each point of the horizon. The rate at that hour was 450 to 600 per minute, as near as I could judge lying on my back on the steamer's awning. It is probable, however, that I missed a great many. The point of emergence was at one-fifth the distance from γ Andromedæ (Almach) towards β Andromedæ (Mirach). The following night the shower was still plentiful, but I did not count them. The nights have been very clear and beautiful here.

December 1, 1885 ALFRED CARPENTER

Deposits of the Nile Delta

IN the abstract of the Report of the Committee of the Royal Society, on recent borings in the Nile Delta (NATURE, Dec. 10, 1885, p. 142), there is a reference to my "Notes on the Geology of the Nile Valley" (*Geological Magazine*, 1884), which calls for some explanation in the interests of Egyptian geology. When I saw a portion of the borings in Cairo, in the early part of 1884, the work had extended to a depth of only about 40 feet. At a depth of between 30 and 40 feet the boring-rod, after passing through continuous Nile mud, had entered into quicksand, consisting of polished and rounded grains of quartz and other hard rocks (desert sand), and the difficulties incident to this material had for the time arrested the operations. In connection with this and with the insufficiency of the funds on hand for overcoming the difficulties of the work, I wrote a letter at the time to the President of the Royal Society, strongly urging an additional grant, in order that greater depths might be reached.

I then believed, and still believe, that the quicksand marks the true base of the modern Delta alluvium, and corresponds with the similar sand which in certain parts of the Delta protrudes itself from beneath the fluviatile deposit. I did not, however, suppose that this sand rests directly on the rocky floor of the valley. On the contrary, as might be inferred from my short statement in the *Geological Magazine* (July 1884, p. 292 and footnote), I anticipated that below the sand would be found the Pleistocene clays, marls, sands, and concretionary limestones of the "Isthmian" formation seen at El Guisr on the Suez Canal, and the equivalents of which rise from under the alluvium in several places on the sides of the Nile Valley. These also constitute the lower strata of the borings reported by Figari Bey; and it appeared to me that in the colour and texture of the sediment mixed with the lower samples of the sand there were indications of the approach to these deposits.

Though I have not seen the borings between 40 and 80 feet, I still think that the question whether these are modern, or belong to the Pleistocene, remains to be disposed of, and will require comparison of the lower samples, if they can be separated from the mud and sand introduced from above, with the overlying deposit. This may have already been attended to, but if so, the fact is not stated in the published abstract. With reference to such comparisons I would ask particular attention to the chemical character and depth of the specimens containing calcareous concretions, which are characteristic of the Isthmian rather than of the Nilotic formation.

Of course I do not affirm that the modern deposit of the Delta is in no place thicker than 40 feet, on the contrary, on my view of the history of the district, there must be old buried channels of the Nile in which it is much thicker, but it should be possible to recognise these by the character of the material filling them.

The softness of the Nile water and the minutely arenaceous character of the Nile mud, as well as the connection of this with its fertility, have been remarked from the most ancient times; and the microscopic details given by Prof. Judd have done much to give precision to our views on these points. With respect however to the causes and geological significance of these phenomena, the conclusions stated in the abstract seem open to serious objections, suggested by the physical features of the area drained by the Nile, and the conditions under which the fluviatile deposits are laid down. As this subject is of some importance both with reference to the geology of Egypt and general geology, I would ask your permission to refer to it in a second short communication. J. WILLIAM DAWSON

McGill College, Montreal, December 24, 1885

The Discovery of the Source of the Mississippi

IT is a matter of little importance or interest in what spot is located the ultimate spring of the longest branch of even the greatest river. Especially is this the case with the Mississippi, where it may easily be an open question which of a dozen branches is the longest, when traced through its innumerable lakes and windings. By common consent, however, a certain branch of the Mississippi has been assumed as the river proper, and its head as Lake Itasca, in northern central Minnesota. The river was explored to this point, and the lake discovered in 1832 by Schoolcraft, who published a map of the lake, and of the river from this point downwards. He spent but one night on the lake, and did not explore its tributaries. Four years later Nicollet led an expedition to the head waters of this stream, reached Lake Itasca, and spent several days in making a thorough exploration of the country about it. In his narrative, published in 1841, he gives a full description of the tributaries to the lake which constituted, according to general acceptation, the extreme head waters of the river. The report is accompanied by a map, on which the geographic features described in the narrative are delineated, and which agrees in general with later and more accurate maps.

During the half century which has passed since the time of these explorers, settlement has crowded upon this region, railroads have been built in close proximity to it, and the country has been explored in every direction in the interest of the lumber industry. Furthermore, in 1876, the surveys of the General Land Office were extended over it. Lines were run at intervals of a mile over the whole region, and every lake and pond of any importance was mapped by traverse survey. In short, the country has long since ceased to be a *terra incognita*.

It is therefore with astonishment, not unmixed with a feeling akin to disgust, that we read in the daily papers, in certain magazines, and finally in the *Journal* of the Royal Geographical Society, an account of the alleged "discovery" of the source of the Mississippi, made by a Capt. Glazier, in the summer of 1881. It appears from his narrative, published in great fulness of detail in the *American Meteorological Journal*, September to December, 1884, that his expedition started at St. Paul and pushed its way manfully by rail and stage to the Leech Lake Indian agency. After obtaining at this place a full complement of men and material (except provisions) for a life in the wilderness, they started westward for Lake Itasca. They fortunately escaped all the perils of the journey, and arrived there on the third day safely. Coasting along the shore of the lake, they found a stream coming in at the head of the south-west arm, up which they journeyed, some two hundred yards, when they entered a second lake, which Capt. Glazier claims to be the ultimate source of the Mississippi, and to which, probably in virtue of his heroic achievement in being paddled to it, he claims the right to give his own name. The failure of provisions prevented him from making any further exploration or discovery, and the expedition returned to settlements.

It appears from the explorer's description and from the extremely incorrect map which accompanies his narrative—made, as he naively informs the reader, from information furnished by his Indian guide—that his so-called Glazier Lake is identical with a lake in Township 143 north, Range 36 west, which had been carefully mapped by traverse survey by the General Land Office in 1876, or five years prior to his "discovery." This lake, or pond, has an area of about half a square mile. On the Land Office plat it is called Elk Lake, and its connection with Lake Itasca is plainly indicated. By a mere inspection of this plat Capt. Glazier might have made his discovery, and thus have avoided all the hardships and labours of his perilous journey. Since his claim to the discovery of this lake must be considered as altogether baseless, his desire that his name shall be for ever associated with it as the source of the Mississippi River is preposterous, especially as he cannot be ignorant of the above facts. HENRY GANNETT

Washington, D.C.

Chætoderma

YOUR biological readers will probably be interested to learn that I dredged a specimen of *Chætoderma* last August off the south end of the Isle of Man from a depth of about 20 fathoms. It is about 1·5 cm. in length, and differs somewhat in shape from both *Chætoderma nitidulum*, Lovén, and the new species (*C. militare*, Selenka) found during the *Challenger* Expedition. The calcareous spicules are also different from those of both the previously described species, but they seem to vary considerably in shape. The specimen—along with the other Vermes obtained during the various dredging expeditions carried on last summer by the members of the Liverpool Marine Biology Committee—has been placed in the hands of Mr. R. J. Harvey Gibson, M.A., for detailed examination, and will be described in the First Report upon the Fauna of Liverpool Bay, to be published shortly. W. A. HERDMAN

University College, Liverpool, December 30, 1885

A Solar Halo

AT about noon on this day a fine halo with its mock suns was well seen at the Radcliffe Observatory. Measurements of the vertical radii of the first circle gave 22° 24′, whilst the angular distance between the true and mock suns was 22° 30′. The radius of the second circle was rather difficult to determine, but the mean of several measures gave 46° 40′. The inverted arcs at the vertices of the two circles were clearly seen. The zenith distance of the sun's centre was nearly 75° at the time of the observation. E. J. STONE, Radcliffe Observer

Radcliffe Observatory, Oxford, December 30, 1885

Ventilation

MR. FLETCHER's letter in your issue of December 17 (p. 153) illustrates the difficulties encountered by people who adopt patent ventilators and so-called systems of ventilation without considering the natural laws ruling the flow of currents of air.

The exit-shafts recommended by the writer of your article on the subject, as he himself confesses, may act as inlets, and generally do, if there is no other free inlet for air. This there seldom is in cold weather when the windows are closed, unless a hot-air grate on the Galton or other model is adopted. There is very little objection to running the exit-tube from the chandelier into the chimney flue, on the same principle as that of the chimney to each ventilator, now so much used.

I think the writer of your article hardly appreciates the difficulties to be encountered in ventilating an English house or assembly-room. Irrespective of the ignorance of the public generally on the subject, we are met by the fact that in most town houses it is very difficult to place a stove, with proper fresh-air inlet, in the entrance, where it may afford a supply of fresh warmed air to the house. As a rule the nearest flue is a very long way off. Again, fire-places being as a rule on inside walls in such houses, the flue to supply a hot-air grate (by far the best method of warming) has to be very long, and there is difficulty in arranging for its due cleansing.

Your correspondent speaks of expense being no object in the erection of public buildings. This is far from my experience. In the cases of churches, schools, and assembly-rooms, the question of ventilation is entirely bound up with that of heating, and in conversation with various makers of heating apparatus I have found their views quite unanimous on the peculiarities of building Committees on this subject. The lowest tender is as a rule accepted, and this never provides for ventilation. They are asked to heat only.

The real objection to ventilation in large rooms is the cost of the necessary heating apparatus. For instance, a large concert-room has recently been erected in this neighbourhood to seat 3800 persons, with a cubical content of 514,800 feet.

Now to warm this in the ordinary manner by hot-water pipes would require about 2600 feet of four-inch piping. But to supply a thousand feet of air per head, heated from 30° to 60° Fahr. would, according to the formula given in Hood's work, require no less than 10,600 feet, or more than four times the amount, while the space occupied by more than two miles of large piping would have to be taken into consideration.

No doubt the heating could be done more economically by steam coils or large stoves if care be taken not to over-heat the air.

Until ventilation is considered as necessary as drainage, and is paid for accordingly, and till failure on the part of architect and builder to secure it is visited with as severe penalties as failure in points of construction or design, I see no chance of improvement on the present state of chaos. Leeds, December 22, 1885

Travellers' Snake-Stories

TRAVELLERS' "stories" are not expected to be quite matter-of-fact. One of the best of these jokes occurs in an article on "Travellers' Snake-Stories" in the December number of *Good Words*. Among the natural enemies of snakes the mongoose is thus described:—

"The mongoose, a bird known as the kingfisher of Australia, and secretary-bird of Africa, is well known in some of the West Indian Islands almost always to come off victorious in its encounters with the rattlesnake, and it has even been proposed to breed it specially for its extirpation."

From the use of the singular number in the above extract it is clear that only one animal is intended to be described, and that one is a *bird*. Next follows an interesting description in considerable detail (quoted from the *Standard* of January 22, 1883), of fights between the *Indian* mongoose and the Indian cobra in Lucknow, ending with the sentence:—

"He adds that these birds make affectionate pets," &c.

This is the best joke of all. It may be that the Australian kingfisher and African secretary-bird are locally called "mongoose" (this is not within the present writer's experience), but the *Indian* mongoose is a small animal, in shape very like a weasel or a ferret. It is impossible that the writer in the *Standard* (who is stated to have himself arranged the mongoose and cobra duels) could have described the mongoose as a *bird*. What does the man mean? ALLAN CUNNINGHAM

Blackbird with White Feather

I NOTICE a letter from Mr. Murphy in your issue of December 24, 1885, about a blackbird with a white feather in its tail. Allow me to say that last month I saw a cock blackbird with a pure white tail; the rest of its plumage was natural. I saw it very distinctly, as it was flying away from me at the time, not more than ten yards off when I first noticed it, with its tail extended; I saw it again last week, within a few feet of the same place, this time running under a gate. My wife says she saw a similar bird, at the same spot, about a year ago. THOMAS J. BUSK

Ford's Grove, Winchmore Hill, January 4

IT may interest your correspondent, Mr. J. J. Murphy, to know that for the last two years we have had a cock blackbird about our garden with a patch of pure white on each side of the head. E. BROWN

Further Barton, Cirencester, January 3

DURING the frost of January 1880 I frequently noticed a hen blackbird with several white feathers on the head, breast, and back. It was quite tame, and came for food every day.

Hartford, Cheshire, December 30, 1885 E. K.

ON THE METHOD OF RECIPROCANTS AS CONTAINING AN EXHAUSTIVE THEORY OF THE SINGULARITIES OF CURVES [1]

IT is now two years and seven days since a message by the Atlantic cable containing the single word "elected" reached me in Baltimore informing me that I had been appointed Savilian Professor of Geometry in Oxford, so that for three weeks I was in the unique position of filling the post and drawing the pay of Professor of Mathematics in each of two Universities: one, the oldest and most renowned, the other—an infant Hercules—the most active and prolific in the world, and which realises what only existed as a dream in the mind of Bacon—the House of Solomon in the New Atlantis.

To Johns Hopkins, who endowed the latter, and in conjunction with it a great Hospital and Medical School, between which he divided a vast fortune accumulated

[1] Inaugural Lecture of Prof. Sylvester, F.R.S., delivered before the University of Oxford, December 12, 1885.

during a lifetime of integrity and public usefulness, I might address the words familiarly applied to one dear to all Wykehamists:—

> "Qui condis lævâ, qui condis collegia dextrâ,
> Nemo tuarum unam vicit utraque manû."

The chair which I have the honour to occupy in this University is made illustrious by the names and labours of its munificent and enlightened founder, Sir Henry Saville; of Thomas Briggs, the second inventor of logarithms; of Dr. Wallis, who, like Leibnitz, drove three abreast to the temple of fame—being eminent as a theologian, and as a philologer, in addition to being illustrious as the discoverer of the theorem connected with the quadrature of the circle named after him, with which every schoolboy is supposed to be familiar, and as the author of the "Arithmetica Infinitorum," the precursor of Newton's "Fluxions"; of Edmund Halley, the trusted friend and counsellor of Newton, whose work marks an epoch in the history of astronomy, the reviver of the study of Greek geometry and discoverer of the proper motions of the so-called fixed stars; and by one in later times not unworthy to be mentioned in connection with these great names, my immediate predecessor, the mere allusion to whom will, I know, send a sympathetic thrill through the hearts of all here present, to whom he was no less endeared by his lovable nature than an object of admiration for his vast and varied intellectual requirements, whose untimely removal, at the very moment when his fame was beginning to culminate, cannot but be regarded as a loss, not only to his friends and to the University for which he laboured so strenuously, but to science and the whole world of letters.

As I have mentioned, the first to occupy this chair was that remarkable man Thomas Briggs, concerning whose relation to the great Napier of Merchiston, the fertile nursery of heroes of the pen and the sword, an anecdote, taken from the Life of Lilly, the astrologer, has lately fallen under my eyes, which, with your permission, I will venture to repeat:—

"I will acquaint you (says Lilly) with one memorable story related unto me by John Marr, an excellent mathematician and geometrician, whom I conceive you remember. He was servant to King James and Charles the First. At first, when the lord Napier, or Marchiston, made public his logarithms, Mr. Briggs, then reader of the astronomy lectures at Gresham College, in London, was so surprised with admiration of them, that he could have no quietness in himself until he had seen that noble person the lord Marchiston, whose only invention they were: he acquaints John Marr herewith, who went into Scotland before Mr. Briggs, purposely to be there when those two so learned persons should meet. Mr. Briggs appoints a certain day when to meet at Edinburgh; but failing thereof, the lord Napier was doubtful he would not come. It happened one day as John Marr and the lord Napier were speaking of Mr. Briggs: 'Ah John (said Marchiston), Mr. Briggs will not now come.' At the very moment one knocks at the gate; John Marr hastens down, and it proved Mr. Briggs to his great contentment. He brings Mr. Briggs up into my lord's chamber, where almost *one quarter of an hour was spent*, each beholding other almost with admiration *before one word was spoke*. At last Mr. Briggs began: 'My lord, I have undertaken this long journey purposely to see your person, and to know by what engine of wit or ingenuity you came first to think of this most excellent help into astronomy, viz. the logarithms; but, my lord, being by you found out, *I wonder nobody else found it out before*, when now known it is so easy.' He was nobly entertained by the lord Napier; and every summer after that, during the lord's being alive, this venerable man Mr. Briggs went purposely into Scotland to visit him."[1]

Some apology may be needed, and many valid reasons might be assigned, for the departure, in my case, from the usual course, which is that every professor on his appointment should deliver an inaugural lecture before commencing his regular work of teaching in the University. I hope that my remissness, in this respect, may be condoned if it shall eventually be recognised that I have waited, before addressing a public audience, until I felt prompted to do so by the spirit within me craving to find utterance, and by the consciousness of having something of real and more than ordinary weight to impart, so that those who are qualified by a moderate amount of mathematical culture to comprehend the drift of my discourse, may go away with the satisfactory feeling that their mental vision has been extended and their eyes opened, like my own, to the perception of a world of intellectual beauty, of whose existence they were previously unaware.

This is not the first occasion on which I have appeared before a general mathematical audience, as the messenger of good tidings, to announce some important discovery. In the year 1859 I gave a course of seven or eight lectures at King's College, London, at each of which I was honoured by the attendance of my lamented predecessor, on the subject of "The Partitions of Numbers and the Solution of Simultaneous Equations in Integers," in which it fell to my lot to show how the difficulties might be overcome which had previously baffled the efforts of mathematicians, and especially of one bearing no less venerable a name than that of Leonard Euler, and also laid the basis of a method which has since been carried out to a much greater extent in my "Constructive Theory of Partitions," published in the *American Journal of Mathematics*, in writing which I received much valuable co operation and material contributions from many of my own pupils in the Johns Hopkins University.[1] Several years later, in the same place, I delivered a lecture on the well-known theorem of Newton, which fills a chapter in the "Arithmetica Universalis," where it was stated without proof, and of which many celebrated mathematicians, including again the name of Euler, had sought for a proof in vain. In that lecture I supplied the missing demonstration, and owed my success, I believe, chiefly to merging the theorem to be proved, in one of greater scope and generality. In mathematical research, reversing the axiom of Euclid, and converting the proposition of Hesiod, it is a continual matter of experience, as I have found myself over and over again, that the whole is less than its part. On a later occasion, taking my stand on the wonderful discovery of Peaucellier, in which he had realised that exact parallel motion which James Watt had believed to be impossible, and exhausted himself in contrivances to find an imperfect substitute for, in the steam-engine, I think I may venture to say that I brought into being a new branch of mechanico-geometrical science, which has been, since then, carried to a much higher point by the brilliant inventions of Messrs. Kempe and Hart. I remember that my late lamented friend, the Lord Almoner's Reader of Arabic in this University, subsequently editor of the *Times*, Mr. Chenery, who was present on that occasion in an unofficial capacity, remarked to me after the lecture, which was delivered before a crowded auditory at the Royal Institution, that when they saw two suspended

[1] A very similar story is told of the meeting of Leopardi and Niebuhr in Rome. What Briggs said of logarithms may be said almost in the same words of the subject of this lecture:—"This most excellent help to geometry which, being found out, one wonders nobody else found it out before; when, now known, it is so easy." I quite entered into Brigg's feelings at his interview with Napier when I recently paid a visit to Poincaré in his airy perch in the Rue Gay-Lussac in Paris (will our grandchildren live to see an Alexander Williamson Street in the north-west quarter of London, or an Arthur Cayley Court in Lincoln's Inn, where he once abode?). In the presence of that mighty reservoir of pent-up intellectual force my tongue at first refused its office, my eyes wandered, and it was not until I had taken some time (it may be two or three minutes) to peruse and absorb as it were the idea of his external youthful lineaments that I found myself in a condition to speak.

[1] In one of those lectures, two hundred copies of the notes for which were printed off and distributed among my auditors, I founded and developed to a considerable extent the subject since rediscovered by M. Halphen under the name of the Theory of Aspects.

opposite Peaucellier cells, coupled toe-and-toe together, swing into motion, which would have been impossible had not the two connected moving points each described an accurate straight line, "the house rose at you." [The lecture merely illustrated experimentally two or three simple propositions of Euclid, Book III.].

The matter that I have to bring before your notice this afternoon is one far bigger and greater, and of infinitely more importance to the progress of mathematical science, than any of those to which I have just referred. No subject during the last thirty years has more occupied the minds of mathematicians, or lent itself to a greater variety of applications, than the great theory of Invariants. The theory I am about to expound, or whose birth I am about to announce, stands to this in the relation not of a younger sister, but of a brother, who, though of later birth, on the principle that the masculine is more worthy than the feminine, or at all events, according to the regulations of the Salic law, is entitled to take precedence over his elder sister, and exercise supreme sway over their united realms. Metaphor apart, I do not hesitate to say that this theory, *minor natu potestate major*, infinitely transcends in the extent of its subject-matter, and in the range of its applications, the allied theory to which it stands in so close a relation. The very same letters of the alphabet which may be employed in the two theories, in the one may be compared to the dried seeds in a botanical cabinet, in the other to buds on the living branch ready to burst out into blossom, flower, and fruit, and in their turn supply fresh seed for the maintenance of a continually self-perpetuating cycle of living forms. In order that I may not be considered to have lost myself in the clouds in making such a statement, let me so far anticipate what I shall have to say on the meaning of Reciprocants and their relation to the ordinary Invariantive or Covariantive forms by taking an instance which happens to be common (or at least, by a slight geometrical adjustment, may be made so) to the two theories. I ask you to compare the form

$$a^2d - 3abc + 2b^3$$

as it is read in the light of the one and in that of the other. In the one case the a, b, c, d stand for the coefficients of a so-called Binary Quantic, and its evanescence serves to express some particular relation between three points lying in a right line. In the other case the letters are interpreted to mean the successive differential derivatives of the 2nd, 3rd, 4th, 5th orders of one Cartesian co-ordinate of a curve in respect to the other. The equation expressing this evanescence is capable of being integrated, and this integral will serve to denote a relation between the two co-ordinates which furnishes the necessary and sufficient condition in order that the point of the curve of any or no specified order (for it may be transcendental) to which the co-ordinates may refer, may admit of having, at the point where the condition is satisfied, a contact with a conic of a higher order than the common. In the one case the letters employed are dead and inert atoms; in the other they are germs instinct with motion, life, and energy.

A curious history is attached to the form which I have just cited, one of the simplest in the theory, of which the narrative may not be without interest to many of my hearers, even to those whose mathematical ambition is limited to taking a high place in the schools.

At pp. 19 and 20 of Boole's "Differential Equations" (edition of 1859) the author cites this form as the lefthand side of an equation which he calls the "Differential Equation of lines of the second order," and attributes it to Monge, adding the words, "But here our powers of geometrical interpretation fail, and results such as this can scarcely be otherwise useful than as a registry of integrable forms." In this vaticination, which was quite uncalled for, the eminent author, now unfortunately deceased, proved himself a false prophet, for the form referred to is among the first that attracts notice in crossing the threshold of the subject of Reciprocants, and is but one of a crowd of similar and much more complicated expressions, no less than it, susceptible of geometrical interpretation and of taking their place on the register of integrable forms. A friend, with whom I was in communication on the subject, and whom I see by my side, remarked to me, in reference to this passage:—"I cannot help comparing a certain passage in Boole to Ezekiel's valley of the dry bones: 'The valley was full of bones, and lo, they were very dry.' The answer to the question, 'Can these bones live?' is supplied by the advent of the glorious idea of the Reciprocants; and the grand invocation, 'Come from the four winds, O breath, and breathe upon these slain, that they may live,' may well be used here. That they will 'live and stand up upon their feet an exceeding great army' is what we may expect to happen." This, as you will presently see, is just what actually has happened.

Not knowing where to look in Monge for the implied reference, I wrote to an eminent geometer in Paris to give me the desired information; he replied that the thing could not be in Monge, for that M. Halphen, who had written more than one memoir on the subject of the differential equation of a conic, had made nowhere any allusion to Monge in connection with the subject. Hereupon, as I felt sure that a reference contained in repeated editions of a book in such general use as Boole's "Differential Equations" was not likely to be erroneous, I addressed myself to M. Halphen himself, and received from him a reply, from which I will read an extract:—

"En premier lieu, c'est une chose nouvelle pour moi que l'équation différentielle des coniques se trouve dans Boole, dont je ne connais pas l'ouvrage. Je vais, bien entendu, le consulter avec curiosité. Ce fait a échappé à tout le monde ici, et l'on a cru généralement que j'avais le premier donné cette équation. *Nil sub sole novi!* Il m'est naturellement impossible de vous dire où la même équation est enfouie parmi les œuvres de Monge. Pour moi, c'est dans *Le Journal de Math.* (1876), p. 375, que j'ai eu, je crois, la première occasion de développer cette équation sous la forme même que vous citez; et c'est quand je l'ai employée, l'année suivante, pour le problème *sur les lois de Kepler* (*Comptes rendus*, 1877, t. lxxxiv. p. 939), que M. Bertrand l'a remarquée comme neuve. Ce qui vous intéresse plus, c'est de connaître la forme simplifiée sous laquelle j'ai donné plus tard cette équation dans le *Bulletin* de la Société Mathématique. C'est sous cette dernière forme que M. Jordan la donne dans son cours de l'École Polytechnique" (t. i. p. 53).

All my researches to obtain the passage in Monge referred to by Boole have been in vain.[1]

I will now proceed to endeavour to make clear to you what a Reciprocant means: the above form, which may be called the *Mongian*, would afford an example by which to illustrate the term; but I think it desirable to begin with a much easier one. Consider then the simple case of a single term, the second derivative of one variable, y, in respect to another, x. Every tyro in algebraical geometry knows that this, or rather the fact of its evanescence, serves to characterise one or more points in a curve which possess, so to say, a certain indelible and intrinsic character, or what is technically called a singularity; in this case an inflexion such as exists in a capital S, or Hogarth's line of beauty.

If we invert the two variables, exchanging, that is to say, one with the other, the fact of this indelibility draws with

1 Search has been made in the collected works of Monge and in manuscripts of his own or Prony in the library of the Institute, but without effect. I have also made application to the Universal Information Society, who undertake to answer "every conceivable question," but nothing has so far come of it. Perhaps until the citation from Monge is verified it will be safer in future to refer to the so-called Mongian as the Boole-Mongian. It may be regarded as the starting-point of the Differential Invariant Theory, as the Schwarzian is of the deeper-lying and more comprehensive Reciprocant Theory.

it the consequence that in general these two reciprocal functions must vanish together, and as a fact each is the same as the other multiplied or divided by the third power of the first derivative of the one variable with respect to the other taken negatively. In this case we are dealing with a single derivative and its reciprocal. The question immediately presents itself whether there may not be a combination of derivatives possessing a similar property. We know that no *single* derivative except the second does.

Such a combination actually presents itself in a form which occurs in the solution of Differential Equations of the second order, the form

$$\frac{dy}{dx}\cdot\frac{d^3y}{dx^3}-\frac{3}{2}\left(\frac{d^2y}{dx^2}\right)^2,$$

which, after the name of its discoverer, Schwarz, we may agree to call a Schwarzian (Cayley's "Schwarzian Derivative"[1]). If in this expression the x and y be interchanged, its value, barring a factor consisting of a power of the first derivative, remains unaltered, or, to speak more strictly, merely undergoes a change of algebraical sign. We may now arrive at the generalised conception of an algebraical function of the derivatives of one variable in respect to another, which, if we agree to pay no regard to the algebraical sign, or to any power of the first derivative that may appear as a factor, will remain unaltered when the dependent and independent variables are interchanged one with another; and we may agree to call any such function a Reciprocant.

But here an important distinction arises—there are Reciprocants such as the one I first mentioned, $\frac{d^2y}{dx^2}$, or such as the Mongian to which allusion has been made in the letter from M. Halphen, in which the second and higher differential derivatives alone appear, the first differential derivative not figuring in the expression. These may be termed Pure Reciprocants. Thus I repeat $\frac{d^2y}{dx^2}$, and

$$9\left(\frac{d^2y}{dx^2}\right)^2\cdot\frac{d^5y}{dx^5}-45\frac{d^2y}{dx^2}\cdot\frac{d^3y}{dx^3}\cdot\frac{d^4y}{dx^4}+40\left(\frac{d^3y}{dx^3}\right)^3$$

are pure reciprocants. Those from which the first derivative $\frac{dy}{dx}$ is not excluded may be called Mixed Reciprocants. An example of such kind of Reciprocants is afforded by the Schwarzian above referred to. This distinction is one of great moment, for a little attention will serve to make it clear that every pure reciprocant expressed in terms of x and y marks an intrinsic feature or singularity in the curve, whatever its nature may be, of which x and y are the co-ordinates; for if in place of the variables (x, y) any two linear functions of these variables be substituted, a pure reciprocant, by virtue of its reciprocantive character, must remain unaltered save as to the immaterial fact of its acquiring a factor containing merely the constants of substitution.[2]

The consequence is that every pure reciprocant corresponds to, and indicates, some singularity or characteristic feature of a curve, and *vice versâ* every such singularity of a general nature and of a descriptive (although not necessarily of a projective) kind, points to a pure reciprocant.

Such is not the case with mixed reciprocants. They will not in general remain unaltered when linear substitutions are impressed upon the variables. Is it then necessary, it may be asked, to pay any attention to mixed reciprocants; or may they not be formally excluded at the very threshold of the inquiry? Were I disposed to put the answer to this question on mere personal grounds, I feel that I should be guilty of the blackest ingratitude, that I should be kicking down the ladder by which I have risen to my present commanding point of view, if I were to turn my back on these humble mixed reciprocants, to which I have reason to feel so deeply indebted; for it was the putting together of the two facts of the substantial permanence under linear substitutions impressed upon the variables of the Schwarzian form and the simpler one which marks the inflexions of a curve—it was, if I may so say, the collision in my mind of these two facts—that kindled the spark and fired the train which set my imagination in a blaze by the light of which the whole horizon of Reciprocants is now illumined.

But it is not necessary for me to defend the retention of mixed reciprocants on any such narrow ground of personal predilection. The whole body of Reciprocants, pure and mixed, form one complete system, a single garment without rent or seam, a complex whole in which all the parts are inextricably interwoven with each other. It is a living organism, the action of no part of which can be thoroughly understood if dissevered from connection with the rest.

It was in fact by combining and interweaving mixed reciprocants that I was led to the discovery of the pure binomial reciprocant, which comes immediately after the trivial monomial one,—the earliest with which I became acquainted, and of the existence of compeers to which I was for some time in doubt, and only became convinced of the fact after the discovery of the Partial Differential Equation, the master-key to this portion of the subject, which gives the means of producing them *ad libitum* and ascertaining all that exist of any prescribed type. Of this partial differential equation I shall have occasion hereafter to speak; but this is not all, for, as we shall presently see, mixed reciprocants are well worthy of study on their own account, and lead to conclusions of the highest moment, whether as regards their applications to geometry or to the theory of transcendental functions and of ordinary differential equations.

The singularities of curves, taking the word in its widest acceptation, may be divided into three classes: those which are independent of homographic deformation and which remain unaltered in any perspective picture of the curve; those which, having an express or tacit reference to the line at infinity, are not indelible under perspective projection, but using the word descriptive with some little latitude may, in so far as they only involve a reference to the line at infinity as a line, be said to be of a purely descriptive character; and, lastly, those which are neither projective nor purely descriptive, having relation to the points termed, in ordinary parlance, "circular points at infinity" [for which the proper name is "centres of infinitely distant pencils of rays," *i.e.* pencils, every ray of which is infinitely distant from every point external to it]. Such, for instance, would be the character of points of maximum or minimum curvature, which, as we shall see, indicate, or are indicated by, that particular class of Mixed to which I give the name of "Orthogonal Reciprocants." All purely descriptive singularities alike, whether pro-

[1] More strictly speaking this is Cayley's Schwarzian derivative cleared of fractions—it may well be called the Schwarzian (see my note on it in the *Mathematical Messenger* for September or October past). Prof. Greenhill in regard to the Schwarzian derivative proper writes me as follows:—

"I found the reference in a footnote to p. 74 of Klein's 'Vorlesungen über das Ikosaëder, &c.,' in which Klein thanks Schwarz for sending him the reference to a paper by Lagrange, 'Sur la construction des cartes géographiques' in the *Nouveaux Mémoires de l'Académie de Berlin*, 1779. Compare also Schwarz's paper in Bd. 75 of *Borchardt's Journal*, where further literary notices are collected together. Klein says further that in the 'Sächsischen Gesellschaft von Januar 1883,' he has considered the inner meaning (*innere bedentung*) of the differential equation $\frac{\eta'''}{\eta}-\frac{3}{2}\left(\frac{\eta''}{\eta'}\right)^2=f(\eta)$, where $\eta'=\frac{d\eta}{dz}$ . . . ."

There are two papers by Lagrange, one immediately following the other, "Sur la construction des cartes géographiques," but I have not been able to discover the Schwarzian derivative in either of them.

[2] The form as it stands shows that for y a linear function of x and y may be substituted; and the form *reciprocated* (by the interchange of x and y) shows that a similar substitution may be made for x. Hence arbitrary linear substitutions may be simultaneously impressed as x and y without inducing any change of form.

jective or non-projective, are indicated by pure reciprocants, and are subject to the same Partial Differential Equation; just as, in the Theory of Binary Quantics, Invariants, although under one aspect they may be regarded as a self-contained special class, admit of being and are most advantageously studied in connection with, and as forming a part of, the whole family of forms commonly known by the name of "semi-, or subinvariants," but which I find it conduce to much greater clearness of expression and avoidance of ambiguity or periphrasis to designate as Binariants.

The question may here be asked, How, then, are projective and non-projective pure reciprocants to be discriminated by their external characters?

I believe that I know the answer to this question, which is, that the former are subject to satisfy a second partial differential equation of a certain simple and familiar type, but this is a matter upon which it is not necessary for me to enter on the present occasion.[1] It is enough for our present purpose to remark that every projective pure reciprocant must, so to say, be in essence a masked ternary covariant. For instance, if we take the simplest of all such, viz. a, i.e. $\frac{d^2y}{dx^2}$, we have

$$\frac{d^2y}{dx^2}\cdot\left(\frac{d\phi}{dy}\right)^3 = \begin{vmatrix} \frac{d^2\phi}{dx^2} & \frac{d^2\phi}{dxdy} & \frac{d\phi}{dx} \\ \frac{d^2\phi}{dxdy} & \frac{d^2\phi}{dy^2} & \frac{d\phi}{dy} \\ \frac{d\phi}{dx} & \frac{d\phi}{dy} & 0 \end{vmatrix}$$

which, for facility of reference, let me call M. Obviously we might instead of $a = 0$ substitute $M = 0$ to mark an inflexion. And now if we write Φ as the completed form of ϕ, when made homogeneous by the substitution of z for unity; and if we suppose it to be of n dimensions in x, y, z, and call its Hessian H, we shall obtain the syzygy

$$(n-1)^2\left(\frac{d\phi}{dy}\right)^3 \cdot a + H + \left\{\frac{d^2\Phi}{dx^2}\cdot\frac{d^2\Phi}{dy^2} - \left(\frac{d^2\Phi}{dxdy}\right)^2\right\}\Phi = 0.$$

Hence the system $\Phi = 0$, $a = 0$, will be in effect the same as the system $\Phi = 0$, $H = 0$, and in this sense a may be said to carry H as it were in its bosom. And so in general every pure projective reciprocant may, in the language of insect transformation, be regarded as passing, so to say, first from the grub to the pupa or chrysalis, and from this again, divested of all superfluous integuments, to the butterfly or imago state.

Non-projective pure reciprocants undergo only one such change. There is no possibility of their ever emerging into the imago—their development being finally arrested at the chrysalis stage.

It would, I think, be an interesting and instructive task to obtain the imago or Hessianised transformation of the Mongian, but I am not aware that any one has yet done, or thought of doing, this.[2] It seems to me that by substituting Reciprocants in lieu of Ternary Covariants we are as it were stealing a dimension from space, inasmuch as Reciprocants, *i.e.* Ternary Covariants in their undeveloped state, are closely allied to, and march *pari passu* with, the familiar forms which appertain to merely binary quantics.

I will now proceed to bring before your notice the general partial differential equation which supplies the necessary and sufficient condition to which all pure reciprocants are subject.

It is highly convenient to denote the successive derivatives

$$\frac{dy}{dx^2}, \frac{dy}{dx^3}, \frac{dy}{dx^4}, \ldots$$

by the simple letters $a, b, c, \ldots$

The first derivative $\frac{dy}{dx}$ plays so peculiar a part in this theory that it is necessary to denote it by a letter standing aloof from the rest, and I call it τ. This last letter, I need not say, does not make its appearance in any pure reciprocant. This being premised, I invite your attention to the equation in question, in which you will perceive the symbols of operation are separated from the object to be operated upon.

Writing $V = 3a^2\delta + 10ab\delta_c + (15ac + 10b^2)\delta_d + \ldots$ and calling any pure reciprocant R,

$$I'R = 0$$

is the equation referred to.

I cannot undertake, within the brief limits of time allotted to this lecture, to explain how this operation, or, as it may be termed, this annihilator V is arrived at. The table of binomial coefficients, or rather half-series of binomial coefficients, shown in Chart 4, will enable you to see what is the law of the numerical coefficients of its several terms. Let the words *weight, degree, extent* (extent, you will remember, means the number of places by which the most remote letter in the form is separated from the first letter in the alphabet) of a pure reciprocant signify the same things as they would do if the letters $a, b, c, \ldots$ referred, according to the ordinary notation, to Binariants instead of to Reciprocants. The number of binariants linearly independent of each other whose weight, extent, and order are w, i, j is given by the partition formula $(w; i, j) - (w-1; i, j)$ where in general $(w; i, j)$ means the number of ways of partitioning w into i or fewer parts none greater than j. It follows immediately from the mere form of V that the corresponding formula in the case of Reciprocants of a given type $w.i.j$ will be $(w; i, j) - (w-1; i+1, j)$ the augmentation of i in the second term of the formula being due to the fact that, whereas in the partial differential equation for Binariants it is the letters themselves which appear as coefficients, it is quadratic functions of these in the case of Reciprocants. From the form of V we may also deduce a rigorous demonstration of the existence of Reciprocants strictly analogous to those with which you are familiar in the Binarian Theory, which are pictured in Chart 2, and are now usually designated as Protomorphs, as being the forms by the interweaving of which with one another (or rather by a sort of combined process of mixture and precipitation), all others, even the irreducible ones, are capable of being produced. The corresponding forms for Reciprocants you will see exhibited in the same table. Each series of Protomorphs may of course be indefinitely extended as more and more letters are introduced. In the table I have not thought it necessary to go beyond the letter g. You also know that besides Protomorphs there are other irreducible forms, the organic radicals, so to say, into which every compound form may be resolved, always limited in number, whatever the number of letters or primal elements we may be dealing with. The same thing happens to Reciprocants as you will notice in the comparative table in Chart 2. Without going into particulars, I will ask you to take from me upon faith the assurance that there is no single feature in the old familiar theory, whether it relates to Protomorphs, to Groundforms, to Perpetuants, to Factorial constitution, to Generating Functions, or whatever else sets its stamp upon the one, which is not counterfeited by and reproduced in the parallel theory.

[1] In Paris, from which I correct the proofs, I have succeeded in reducing this conjecture to a certainty and in establishing the marvellous fact that every Projective Reciprocant, or, which is the same thing, every Differential Invariant, is, at the same time, an Ordinary Subinvariant. Thus a differential invariant (or projective reciprocant) may be regarded as *a single personality clothed with two distinct natures*—that of a reciprocant and that of a subinvariant.

[2] M. Halphen informs me that this has been done by Cayley in the *Phil Trans.* for 1865, and subsequently in a somewhat simplified form by Painvin, *Comptes rendus*, 1874. But neither of these authors seems to have had the Boole-Mongian objectively before them, so that a slight supplemental computation is wanting to establish the equation between it and the function which either of them finds to vanish at a *sextactic* point

So much—for time will not admit of more—concerning pure reciprocants.

Let me now say a few words *en passant* on Mixed Reciprocants.

Pure Reciprocants, we have seen, are the analogues of Invariants, or else of the leading terms [for that is what are Semi- or Subinvariants] of Covariantive expansions; each is subject to its own proper linear partial differential equation. Mixed Reciprocants are the exact analogues of the coëfficients in such expansions other than those of the leading terms. Starting from the leading terms as the unit point, the coefficients of rank ω are subject to a partial differential equation of order ω; and just so, mixed reciprocants, if involving τ up to the power ω, are subject to a partial differential equation of that same order.

I have alluded to a peculiar class of mixed under the name of "Orthogonal Reciprocants." They are distinguished, as I have proved, by the beautiful property that, if differentiated with respect to τ, the result must be itself a Reciprocant. In Chart 1 you will see this illustrated in the case of a mixed reciprocant $(1 + \tau^2)b - 3\tau a^2$, which serves to indicate the existence of points of maximum and minimum curvature. Its differential coefficient with respect to t is the oft-alluded-to Schwarzian, transliterated into the simpler notation. Proceeding in the inverse order—of Integration instead of Differentiation—I call your attention to a mixed reciprocant, of a very simple character, one which presents itself at the very outset of the theory, viz.—

$$\tau c - 5ab,$$

which, integrated in respect to t between proper limits, yields the elegant orthogonal reciprocant—

$$(\tau^2 + 1)c - 10ab\tau + 15a^3.$$

Expressed in the ordinary notation, this, equated to zero, takes the form—

$$\left\{\left(\frac{dy}{dx}\right)^2 + 1\right\}\frac{d^4y}{dx^4} - 10\frac{dy}{dx}\cdot\frac{d^2y}{dx^2}\cdot\frac{d^3y}{dx^3} + 15\left(\frac{d^2y}{dx^2}\right)^3 = 0.$$

Mr. Hammond has integrated this, treated as an ordinary differential equation, and has obtained the complete primitive expressed through the medium of two related Hyper-Elliptic Functions connecting the variables x and y (see Chart 3). It may possibly turn out to be the case that every mixed reciprocant is either itself an Orthogonal Reciprocant, or by integration, in respect to τ, leads to one.

It will of course be understood that, in interpreting equations obtained by equating to zero an Orthogonal Reciprocant, the variables must be regarded as representing not general but rectangular Cartesian co-ordinates.

Here seems to me to be the proper place for pointing out to what extent I have been anticipated by M. Halphen in the discovery of this new world of Algebraical Forms. When the subject first dawned upon my mind, about the end of October or the beginning of November last, I was not aware that it had been approached on any side by any one before me, and believed that I was digging into absolutely virgin soil. It was only when I received M. Halphen's letter, dated November 25, in relation to the Mongian business already referred to, accompanied by a presentation of his memoirs on Differential Invariants, that I became aware of there existing any link of connection between his work and my own. A Differential Invariant, in the sense in which the term is used by M. Halphen, is not what at first blush I supposed it to be, and as in my haste to repair what seemed to me an omission to be without loss of time supplied, I wrote to M. Hermite it was, in a letter which has been or is about to be inserted in the *Comptes rendus* of the Institute of France; it is not, I say, identical with what I have termed a general pure reciprocant, but only with that peculiar species of Pure Reciprocants to which I have in a preceding part of this lecture referred as corresponding and pointing to Projective Singularities. In his splendid labours in this field Halphen has had no occasion to construct or concern himself with that new universe of forms viewed as a whole, whether of Pure or Mixed Reciprocants, which it has been the avowed and principal object of this lecture to bring under your notice.

I anticipate deriving much valuable assistance in the vast explorations remaining to be made in my own subject from the new and luminous views of M. Halphen, and possibly he may derive some advantage in his turn from the larger outlook brought within the field of vision by my allied investigations.

Let me return for a moment to that simplest class of pure reciprocants which I have called protomorphs. Each of these will be found (as may be shown either by a direct process of elimination, or by integrating the equations obtained by equating them severally to zero, regarded as ordinary differential equations between x and y) each of these, I say, will be found to represent some simple kind of singularity at the point (x, y) of the curve to which these co-ordinates are supposed to refer. Thus, for instance, No. 1 marks a single point of inflexion; No. 2, points of closest contact with a common parabola; No. 3, what our Cayley has called sextactic points, referring to a general conic; No. 4, points of closest contact with a common cubical parabola; and so on. The first and third, it will be noticed, represent projective singularities, and as such, in M. Halphen's language, would take the name of Differential Invariants. The second and fourth, having reference to the line at infinity in the plane of the curve, are of a non-projective character, and as such would not appear in M. Halphen's system of Differential Invariants. It is an interesting fact that every simple parabola, meaning one whose equation can be brought under the form $y = x^{\frac{m}{n}}$, corresponds to a linear function of a square of the third, and the cube of the second protomorph, and consequently will in general be of the sixth degree. In the particular case of the cubical parabola, the numerical parameter of this equation is such that the highest powers of b cancel each other so that the form sinks one degree, and becomes represented by the *Quasi-Discriminant*, No. 4.

This simple instance will serve to illustrate the intimate connection which exists between the projective and non-projective reciprocants, and the advantage, not to say necessity, of regarding them as parts of one organic whole.

It would take me too far to do more than make the most cursory allusion to an extension of this theory similar to that which happens when in the ordinary theory of invariants we pass from the consideration of a single Quantic to that of two or more. There is no difficulty in finding the partial differential equation to double reciprocants which, as far as I have as yet pursued the investigation, appear to be functions of $a, b, c, \ldots$; $a', b', c', \ldots$; and of $(\tau - \tau')$.

The theory of double reciprocants will then include as a particular case the question of determining the singularities of paired points of two curves at which their tangents are parallel, and consequently the theory of common tangents to two curves and of bi-tangents to a single one.

I think I may venture to say that a general pure multiple reciprocant which marks off relative singularities, whether projective or non-projective, of a group of curves, is a function of the second and higher differential derivatives appertaining to the several curves of the group, and of the differences of the first derivatives, whereas in a mixed multiple reciprocant these last-named differences are replaced by the first derivatives themselves. As a particular case, when the group dwindles to an individual and there is only one τ, this letter disappears altogether from the form, for there are no differences of a single quantity.

In the chart (marked No. 2) you will see the table of Protomorphs carried on as far as the letter g inclusive, and will not fail to notice what may be termed the higher organisation of Reciprocantive as compared with ordinary Invariantive Protomorphs; the degrees of the latter oscillate or librate between the numbers 2 and 3, whereas in the former the degree is variable according to a certain transcendental law dependent on the solution of a problem in the Partition of Numbers. Another interesting difference between general Invariants and general Pure Reciprocants consists in the fact that, whilst the number of the former ultimately (*i.e.* when the extent is indefinitely increased) becomes indefinitely great, that of the latter is determinate for any given degree even for an infinite number of letters.

In carrying on the table of protomorphs up to the letter h (see Chart 6) a new phenomenon presents itself, to which, however, there is a perfect parallel in the allied theory. An arbitrary constant enters into the form, its general value being a linear function of U and W (for which see Chart 6). But this is not all. If you examine the terms in both U and W (there are in all twelve such) you will find that these twelve do not comprise all of the same type to which they belong. There is a Thirteenth (a banished Judas), equally *a priori* entitled to admission to the group, but which does not make its appearance among them, viz. b^4d. I rather believe that a similar phenomenon of one or more terms, whose presence might be expected, but which do not appear, presents itself in the allied invariantive theory, but cannot speak with certainty as to this point, as the circumstance has not received, and possibly does not merit, any very particular attention.

Still, in the case before us, this unexpected absence of a member of the family, whose appearance might have been looked for, made an impression on my mind, and even went to the extent of acting on my emotions. I began to think of it as a sort of lost Pleiad in an Algebraical Constellation, and in the end, brooding over the subject, my feelings found vent, or sought relief, in a rhymed effusion, a *jeu de sottise*, which, not without some apprehension of appearing singular or extravagant, I will venture to rehearse. It will at least serve as an interlude, and give some relief to the strain upon your attention before I proceed to make my final remarks on the general theory.

TO A MISSING MEMBER

Of a Family Group of Terms in an Algebraical Formula

Lone and discarded one! divorced by fate,
Far from thy wished-for fellows—whither art flown?
Where lingerest thou in thy bereaved estate,
Like some lost star, or buried meteor stone?
Thou mindst me much of that presumptuous one
Who loth, aught less than greatest, to be great,
From Heaven's immensity fell headlong down
To live forlorn, self-centred, desolate:
Or who, new Heraklid, hard exile bore,
Now buoyed by hope, now stretched on rack of fear,
Till throned Astræa, wafting to his ear
Words of dim portent through the Atlantic roar,
Bade him "the sanctuary of the Muse revere
And strew with flame the dust of Isis' shore."

Having now refreshed ourselves and bathed the tips of our fingers in the Pierian spring, let us turn back for a few brief moments to a light banquet of the reason, and entertain ourselves as a sort of after-course with some general reflections arising naturally out of the previous matter of my discourse. It seems to me that the discovery of reciprocants must awaken a feeling of surprise akin to that which was felt when the galvanic current astonished the world previously accustomed only to the phenomena of machine or frictional electricity. The new theory is a ganglionic one: it stands in immediate and central relation to almost every branch of pure mathematics—to Invariants, to Differential Equations, ordinary and partial, to Elliptic and Transcendental Functions, to Partitions of Numbers, to the Calculus of Variations, and above all to Geometry (alike of figures and of complexes), upon whose inmost recesses it throws a new and wholly unexpected light. The geometrical singularities which the present portion of the theory professes to discuss are in fact the distinguishing *features* of curves; their *technical* name, if applied to the human countenance, would lead us to call a man's eyes, ears, nose, lips, and chin his singularities; but these singularities make up the character and expression, and serve to distinguish one individual from another. And so it is with the so-called singularities of curves.

Comparing the system of ground-forms which it supplies with those of the allied theory, it seems to me clear that some common method, some yet undiscovered, deep-lying, Algebraical principle remains to be discovered, which shall in each case alike serve to demonstrate the finite number of these forms (these organic radicals) for any specified number of letters. The road to it, I believe, lies in the Algebraical Deduction of ground-forms from the Protomorphs.[1] Gordan's method of demonstration, so difficult and so complicated, requiring the devotion of a whole University semester to master, is inapplicable to reciprocants, which, as far as we can at present see, do not lend themselves to symbolic treatment.

How greatly must we feel indebted to our Cayley, who while he was, to say at least, the joint founder of the symbolic method, set the first, and out of England little if at all followed, example of using as an engine that mightiest instrument of research ever yet invented by the mind of man—a Partial Differential Equation, to define and generate invariantive forms.

With the growth of our knowledge, and higher views now taken of invariantive forms, the old nomenclature has not altogether kept pace, and is in one or two points in need of a reform not difficult to indicate. I think that we ought to give a general name—I propose that of Binariants—to every rational integral form which is nullified by the general operator

$$\lambda a d_b + \mu b d_c + \nu c d_d + \ldots .$$

where $\lambda, \mu, \nu, \ldots$ are arbitrary numbers.

This operator, I think, having regard to the way in which its segments link on to one another, may be called the Vermicular.

Binariants corresponding to unit values of $\lambda, \mu, \nu, \ldots$ may be termed standard binariants. Those for which these numbers are the terms of the natural arithmetical series 1, 2, 3, ... Invariantive binariants, which may be either complete or incomplete invariants; these latter are what are usually termed semi- or sub-invariants. I may presently have to speak of a third class of binariants for which the arbitrary multipliers are the numbers 3, 8, 15, 24 ... (the squares of the natural numbers each diminished by unity) which, if the theorem I have in view is supported by the event, will have to be termed Reciprocantive Binariants. But first let me call attention to what seems a breach of the asserted parallelism between the Invariantive and the Reciprocantive theories. In the former we have complete and incomplete invariants, but we have drawn no such distinction between one set of pure reciprocants and another. A parallel distinction does however exist.

If we use w, i, j to signify the weight, extent, and degree of an invariantive form, w is never less than the half product of ij; when equal to it the form is complete. In the case of reciprocants certain observed facts seem to indicate that there exists an analogous but less simple

[1] See the section on the Algebraical Deduction of the Ground-forms of the Quintic in my memoir on Subinvariants in the *American Journal of Mathematics*.

inequality. If this conjecture is verified it is not merely $\frac{ij}{2} - w$, but $\frac{ij}{2} - (j - 2) - w$, which is never negative: and when this is zero, the form may be said to be complete.[1] There would then be thus complete forms in each of the two theories; in the earlier one they take a special name: this is the only difference.

We have spoken of Pure Reciprocants as being either projective or non-projective, but so far have abstained from particularising the external characters by which the former may be distinguished from the latter. I have good reason to suspect that the former are distinguished from the latter by being Binariants; that, in addition to being subject to annihilation by the operator V, they are also subject to annihilation by the Vermicular operator when made special by the use of the numerical multipliers 3, 8, 15 . . . above alluded to, or in other words (as previously mentioned incidentally) are subject to satisfy two simultaneous partial differential equations instead of only one.[2] Projective Reciprocants we have seen are disguised or masked Ternary Covariants —Covariants in the grub, the first undeveloped state. Now ternary covariants are capable, it may or may not be generally known, of satisfying 6 reducible to 2 simultaneous Partial Differential Equations, and at first sight it might be surmised that nothing would be gained by the substitution of the two new for the two old simultaneous partial differential equations. But the fact is not so, for the old partial differential equations are perfectly unmanageable, or at least have never, as far as I know, been handled by any one, for they have to do with a *triangular heap*, whereas the new ones are solely concerned with a *linear series* of co-efficients.

I have alluded to there being a particular form common to the two theories. In the one theory it is the Mongian alluded to in the correspondence, which has been read, with M. Halphen. In the other it is the source of the skew covariant to the cubic. If the latter be subjected to a sort of MacMahonic numerical adjustment, it becomes absolutely identical with the former. Let us imagine that before the invention of Reciprocants an Algebraist happened to have had both forms present to his mind, and had thought of some contrivance for lowering the coefficients of the Mongian written out with the larger coefficients, and had thus stumbled upon this striking fact. It could not have failed to vehemently arouse his curiosity, and he would have set to work to discover, if possible, the cause of this coincidence. He would in all probability have addressed himself to the form which precedes the source alluded to in the natural order of genesis, and have applied a similar adjustment to the much simpler form, $ac - b^2$: having done so he would have tried to discover to what singularity it pointed—but his efforts to do so we know must have been fruitless, and he would have felt disposed to throw down his work in despair, for the intermediate ideas necessary to make out the parallelism would not have been present to his mind. So long as we confine ourselves to Differential Invariants, *i.e.* to projective pure reciprocants, we are like men walking on those elevated ridges, those more than Alpine summits, such as I am told[1] exist in Thibet, where it may be the labour of days for two men who can see and speak to each other to come together. Reciprocants supply the bridge to span the yawning ravine and to bring allied forms into direct proximity.

I have spoken of mixed reciprocants as being subject to satisfy not a linear partial differential equation, but one of a higher order dependent on the intensity, so to say, of its mixedness—the highest power, that is to say, of the first differential derivative which it contains, and it might therefore be supposed that these forms are much more difficult to be obtained than pure reciprocants. But the fact is just the reverse, for as I discovered in the very infancy of the inquiry, and have put on record in the September or October number of the *Mathematical Messenger*, mixed reciprocants may be evolved in unlimited profusion by the application of simple and explicit processes of multiplication and differentiation. From any reciprocant whatever, be it mixed or pure, new mixed ones may be educed infinitely infinite in number, inasmuch as at each stage of the process, arbitrary functions of the first differential derivative may be introduced.

The wonderful fertility of this method of generation excited warm interest on the part of one of the greatest of living mathematicians, the expression of which acted as a powerful incentive to me to continue the inquiry. They may be compared with the shower of December meteors shooting out in all directions and covering the heavens with their brilliant trains, all diverging from one or more fixed radiant-points, the radiant-point in the theory before us being the particular form selected to be operated upon.

The new doctrine which I have endeavoured thus imperfectly to adumbrate has taken its local rise in this University, where it has already attracted some votaries to its side, and will, I hope, eventually obtain the co-operation of many more. I have ventured with this view to announce it as the subject of a course of lectures during the ensuing term.

When I lately had the pleasure of attending the new Slade Professor's inaugural discourse, I heard him promise to make his pupils participators in his work by painting pictures in the presence of his class. I aspire to do more than this—not only to paint before the members of my class, but to induce them to take the palette and brush and contribute with their own hands to the work to be done upon the canvas. Such was the plan I followed at the Johns Hopkins University, during my connection with which I may have published scores of Mathematical articles and memoirs in the journals of America, England, France, and Germany, of which probably there was scarcely one which did not originate in the business of the class-room; in the composition of many or most of them I derived inestimable advantage from the suggestions or contributions of my auditors. It was frequently a chase, in which I started the fox, in which

[1] If this should turn out to be true, the "crude generating fraction" for reciprocants would be almost identical with that of in- and co-variants of the same extent j. The denominators would be absolutely identical; as regards the numerators, while that for invariantive forms is $1 - a^{-1}x^{-2}$ the numerator for reciprocants would be $1 - a^{-2}x^{-2j}$. As I write abroad and from memory there is just a chance that the index of a here given may be erroneous.

[2] As already stated in a previous footnote this conjecture is fully confirmed, my own proof having been corroborated (if it needed corroboration) by another entirely different one invented by M. Halphen, who fully shares my own astonishment at the fact of there being forms (half-horse, half alligator) at once reciprocants and sub-invariants, and as such satisfying two simultaneous partial differential equations.

If instead of denoting the successive differential derivatives (starting from the second $a, b, c, \ldots$ we call them $\frac{a}{1.2}, \frac{b}{1.2.3}, \frac{c}{1.2.3.4}, \ldots$ the two Annihilators will be

$$a\delta_b + 2b\delta_c + 3c\delta_d + 4d\delta_e + \ldots \text{ and}$$

$$4\frac{a^2}{2}\delta_b + 5ac\delta_c + 6(ad + bc)\delta_d + 7\left(ae + bd + \frac{c^2}{2}\right)\delta_e + \ldots$$

the latter being my new operator, the Reciprocator V, accommodated to the above-stated change of notation for the successive differential derivatives.

Hardly necessary is it for me to point out in explanation of the semi-sums $\frac{a^2}{2}, \frac{c^2}{2}, \ldots$ that we may write the MacMahonised V under the form

$$4a^2\delta_b + 5(ac + ca)\delta_c + 6(ac + bc)\delta_d + 7(ac + bd + c^2 + db + ea)\delta_e + \ldots$$

It is to be presumed that in addition to mixed reciprocants (the ocean into which flows the sea of pure reciprocants, as into that again empties itself the river of projective reciprocants) there may exist a theory of forms in which y as well as $\frac{dy}{dx}$ will appear, or, so to say, doubly mixed reciprocants, the most general of all, in which case we must speak of the content of these as the ocean and of the others as sea, river, and brook. Curious is it to reflect that in the theory which as it exists comprises Invariantives, Reciprocants, and Invariantive Reciprocants or Reciprocant Invariantives, the order of discovery was (1) Invariantives (Eisenstein, Boole, &c.); (2) Invariantive Reciprocants (Monge and Halphen); (3) Reciprocants (Schwarz, the author of this lecture).

[1] I think my informant was my friend Dr. Inglis, of the Athenæum Club, who some time ago undertook a journey in the Himalayas in the hopes of coming upon the traces of a lost religion which he thought he had reason to believe existed among mankind in the pre-Glacial period of the earth's history.

we all took a common interest, and in which it was a matter of eager emulation between my hearers and myself to try which could be first in at the death.

During the past period of my professorship here, imperfectly acquainted with the usages and needs of the University, I do not think that my labours have been directed so profitably as they might have been either as regards the prosecution of my own work or the good of my hearers: my attention has been distracted between theories waiting to be ushered into existence and providing for the daily bread of class-teaching. I hope that in future I may be able to bring these two objects into closer harmony and correlation, and think I shall best discharge my duty to the University by selecting for the material of my work in the class-room any subject on which my thoughts may, for the time being, happen to be concentrated, not too alien to, or remote from, that which I am appointed to teach; and thus, by example, give lessons in the difficult art of mathematical thinking and reasoning—how to follow out familiar suggestions of analogy till they broaden and deepen into a fertilising stream of thought—how to discover errors and to repair them, guided by faith in the existence and unity of that intellectual world which exists within us, and is at least as real as that with which we are environed.

The *American Mathematical Journal*, conducted under the auspices of the Johns Hopkins University, which has gained and retains a leading position among the most important of its class, whether measured by the value of its contents or the estimation in which it is held by the Mathematical world, bears as its motto—

πραγμάτων ἔλενχος οὐ βλεπομένων.

I have the pleasure of seeing among my audience this day the most distinguished geometer of Holland, Prof. Schoute, who has done me the signal honour of coming over to England to be present at this lecture, who hospitably entertained me at Groningen (in a vacation visit which I recently paid to his country, the classic soil which has given birth to an Erasmus, a Grotius, a Boerhaave, a Spinoza, a Huyghens, and a Rembrandt), and who was kind enough, in proposing my health at a party where many of his colleagues were present, to say that he felt sure "that I should return to England cheered and invigorated, and would, ere long, light on some discovery which would excite the wonder of the Mathematical world."

I do not venture to affirm, nor to think, that this vaticination has been fulfilled in the terms in which it was uttered, but can most truly say that the discovery, which it has been my good fortune to be made the medium of revealing, has excited my own deepest feelings of ever-increasing wonder rising almost to awe, such as must have come over the revellers who saw the handwriting start out more and more plainly on the wall, or the *scienziati* crowding round the blurred palimpsest as they began to be able to decipher characters and piece together the sentences of the long lost and supposed irrecoverable *De Republicâ.*

When I was at Utrecht, on my way to Groningen, Mr. Grinwis, the Professor of Mathematics at that University, showed me an English book on "Differential Equations," which had just appeared, of which he spoke in high terms of praise, and said it contained over 800 examples. I wrote at once for the book to England, and on seeing it on my arrival, forgetting that it had been ordered, mistook it for a present from the author or publisher, and, what is unusual with me, read regularly into it, until I came to the section on Hyper-geometrical series, where the Schwarzian Derivative (so named by Cayley after Prof. Schwarz) is spoken of.

Perhaps I ought to blush to own that it was new to me, and my attention was riveted by the property it possesses, in common with the more simple form which points to inflexions on curves, of remaining substantially unaltered, of persisting as a factor at least of its altered self, when the variables which enter it are interchanged. Following out this indication, I at once asked myself the question, "ought there not to exist combinations of derivatives of *all* orders possessing this property of reciprocation?" That question was soon answered, and the universe of mixed reciprocants stood revealed before me. These mixed reciprocants, by simple processes of combination, led me to the discovery of the first pure reciprocant, $3b^2 - 5ac$: whereupon I again put the question to myself, "are there, or are there not, others of this form, and if so, what are they?"

In an unexpected manner the question was answered, and my curiosity gratified to the utmost by the discovery of the partial differential equation which is the central point of the theory, and at once discloses the parallelism between it and the familiar doctrine of Invariants. Two principal exponents of that doctrine, who have infused new blood into it, and given it a fresh point of departure—Capt. MacMahon and Mr. Hammond—I have the pleasure of seeing before me. Mr. Kempe, who is also present, has lately entered into and signally distinguished himself in the same field, availing himself in so doing of his profound insight into the subject of linkages, his interest in which I believe I may say received its first impulse from the lecture which he heard me deliver upon it at the Royal Institution in January 1874, on the very night when the Prime Minister for the time being sent round letters to his supporters announcing his intention to dissolve Parliament. Of the two events I have ever regarded the lecture as by far the more important to the permanent interests of society. He has lately applied ideas founded upon linkages to produce a most original and remarkable scheme for explaining the nature of the whole pure body of Mathematical truth, under whatever different forms it may be clothed, in a memoir which has been recommended to be printed in the *Transactions* of the Royal Society, and which, I think, cannot fail when published to excite the deepest interest alike in the Mathematical and the Philosophical worlds.[1]

I also feel greatly honoured by the presence of Prof. Greenhill, who will be known to many in this room from his remarkable contributions to the theory of Hydrodynamics and Vortex Motion, and who has sufficient candour and largeness of mind to be able to appreciate researches of a different character from those in which he has himself gained distinction.

I should not do justice to my feelings if I did not acknowledge my deep obligations to Mr. Hammond for the assistance which he has rendered me, not only in preparing this lecture which you have listened to with such exemplary patience, but in developing the theory; I am indebted to him for many valuable suggestions tending to enlarge its bounds, and believe have been saved, by my conversations with him, from falling into some serious errors of omission or oversight. Saving only our Cayley (who, though younger than myself, is my spiritual progenitor—who first opened my eyes and purged them of dross so that they could see and accept the higher mysteries of our common Mathematical faith), there is no one I can think of with whom I ever have conversed, from my intercourse with whom I have derived more benefit. It would be an immense gain to Science, and to the best interests of the University, if something could be done to bring such men as Mr. Hammond (and, let me add, Mr. Buckheim, who ought never to have been allowed to leave it) to come and live among us. I am sure that with their endeavours added to my own and those of that most able body of teachers and researchers with whom I have the good fortune to be associated—my brother Professors and the Tutorial Staff of the University—we

[1] In his memoir for the *Phil. Trans.* Mr. Kempe contends that any what ever mathematical proposition or research is capable of being represented by some sort of simple or compound linkage. One would like to know by what sort of linkage he would represent the substance of the memoir itself.

could create such a School of Mathematics as might go some way at least to revive the old scientific renown of Oxford, and to light such a candle in England as, with God's grace, should never be put out.[1]

$$\lambda a\delta_b + \mu b\delta_c + \nu c\delta_d + \pi d\delta_e + \ldots$$

Examples

$$a\delta_b + b\delta_c + c\delta_d + d\delta_e + \ldots$$
$$a\delta_b + 2b\delta_c + 3c\delta_d + 4d\delta_e + \ldots$$
$$3a\delta_b + 8b\delta_c + 15c\delta_d + 24d\delta_e + \ldots$$

☞ b^4d does not appear in either U or W.

New College, Oxford, January 6

[1] I have purposely confined myself in my lecture to reciprocants, indicatives of properties of plane curves, but had in view to extend the theory to the case of higher dimensions in space leading to reciprocants involving the differential derivatives of any number of variables $y, z, \ldots$ M. Halphen, with whom I have had the great advantage of being in communication during my stay in Paris, has anticipated me in this part of my plan, and has found that the same method which I have used to obtain the Annihilator V applied to a system of variables leads to an Annihilator of very similar form to V, and at my request will publish his results in a forthcoming number of the *Comptes rendus*. Thus the dominion of reciprocants is already extended over the whole range of forms unlimited in their own number as well as in that of the variables which they contain

THE GEOLOGY OF MALAYSIA, SOUTHERN CHINA, &c.

THERE is a remarkable uniformity in the geology of a very large portion of Southern Asia and its dependent islands, especially from the Malay peninsula, as far east as the Philippines, and as far north as the Chinese continent. In the Malayan peninsula we have an elevated granitic axis. At the base of this there are Palæozoic schists and slates. Above these in a few places there are limestones in detached weathered masses. This limestone is often crystalline, white, blue, and black. In a few cases there are traces of stratification, but no fossils.

In a recent journey through Pahang I found precisely the same formations on the eastern side of the peninsula, with only this addition, that there is a belt of trachytic rocks of modern origin forming detached hills between the main range and the sea.

In Sumatra I learn that there are the same formations from the granite upwards. I cannot confirm this from personal observation, as I have travelled very little in the island. The mountain axis is far from the Straits of Malacca, and difficult of access. As far as I can judge from the geology of such large islands as Bilitou, Bintang, and Banca, the mountains are probably granitic and stanniferous.

Proceeding eastward and northerly, detached granite islands are met with. They are thickly strewn through the intermediate ocean. Those I have seen, such as the north and south Natunas, and other similar outliers, on voyages between Java, Singapore, Borneo, China, Cochin

China, and Siam, are all granitic, with a few Palæozoic slates and schists. To the eastward of the Malay peninsula a few limestone islands are seen, and they are similar in character to the calcareous rocks of the mainland.

It is perhaps needless to draw attention to the extraordinary number of these outliers. They do not show well on a map, as most of them are so very small, but those who travel in these regions can well understand why the early Arabian voyagers called this "the sea of the twelve thousand islands." Granite is the prevailing rock, but I have little doubt that modern trap-rocks form some of the islands. But there is no active volcano amongst them. The nearest point for such phenomena is said to be Formosa, but I think this doubtful. Yet, proceeding north from this large island, along the chain which connects it in an almost unbroken series through the Meiaco group, Liu Kiu and Linschoten Islands, to Japan, we find two active volcanoes (Naka Sima and Sawa Sima, the latter 3400 feet high), which seem to point to a line of disturbance, of which Formosa is a portion.

When we come to Borneo we find the first extensive development of stratified rocks. Though outliers of granite are met occasionally, it is evident that there is a great change in the geology of the coast. I shall confine my observations to what I saw. From Brunei northwards we meet with carbonaceous rocks, brown and yellow sandstones and shales with intercalated grits and conglomerates. The dip varies: sometimes slight, or nearly horizontal, showing but trifling disturbance in this part of the world. It seemed to me as if these carbonaceous rocks were of different ages. Those which line the Brunei River are much older-looking than those of Labuan. At Gaya, and again at Kudat, at the north extremity of Borneo, I saw brownish-yellow sandstones with shales and small seams of coal. The appearance of these beds reminded me much of the Mesozoic carbonaceous rocks of Queensland and New South Wales. At Sandakan or Elopura (North-East Borneo) the present capital of the North Borneo Settlement, there are high cliffs of red and yellow sandstone, which look older than anything I saw on the north or north-eastern coast. Over 600 feet are exposed in one cliff, with no signs of any carboniferous strata.

While at Sandakan I met the Governor's private secretary (Mr. D. D. Daly), who had just returned from a journey of exploration on the Kinebetungen River. He brought down many samples of good coal, besides tin and gold. Amongst the collection were some limestones very like the rocks I had seen in the Malay peninsula. These also form detached mountains. There are fine caves, I am informed, over 600 feet high, and in them are found some of the best kinds of edible birds' nests. Amid the fragments of limestone I recognised a Fenestella and a Stenopora. If this rock is of the same formation as the limestone outliers of the whole of Malaysia, then its age may be for the present considered as Palæozoic, and probably between Devonian and Carboniferous.

After visiting some islands of the Sooloo Archipelago (all volcanic) I went to the Philippines. At Luzon, Mindoro, and some of the larger members of the group, the rocks are principally volcanic. But it would be an error to regard them as exclusively so. There are some areas of stratified rocks with coral and other marine fossils, which are of probably Miocene and Pliocene age. In Mindanao there is gold. I obtained a few fossils from the Miocene beds of the latter island. They were all Foraminifera in a loose friable limestone, including *Orbulina universa*, D'Orb., *Globigerina biloba*, *triloba*, and *bulloides*, D'Orb., *Cristellaria italica*, D'Orb., *Pulvinulina Haueri*, D'Orb., *Rotlaia simplex*, D'Orb., and some others belonging to about twenty different genera. The same species are found in Luzon, and the beds are considered Eocene by Kusrer (see *Boletin de la Carta Geol. del. España*, vol. vii).

One of the most interesting portions of the Philippines is the Calamianes group, a small cluster of islands a short distance south and west of Mindoro. Here we find repeated the main geological features of the Malayan peninsula, with the addition of recent volcanic emanations. To the east of Busuanga (the largest of the group) is the Island of Coron, which presents to the sea a magnificent rampart of limestone cliffs and pinnacles from 600 to 1500 feet high. The aspect is grandly picturesque, but the character of the formation is unmistakably similar to the isolated limestone mountains in the Malayan Peninsula. The rocks are bluish-gray, with apparently a perpendicular stratification, with patches of brilliant colours, including red, yellow, pink, dark and light green, &c. The cliffs descend precipitously into about forty fathoms of water, but at the tidal line they are undermined by the action of the waves in a very cleanly-cut line. Occasionally one may see the natives (Visayas) lowering each other over these dizzy heights to gather the edible birds' nests which here also abound, and form the only valuable export from the islands. The outline of the island is magnificently rugged and irregular, weathered into needles and pinnacles of the most fantastic shape, in the recesses of which there is much pale green grass and patches of darker jungle. Caves are of course numerous. It was the birds'-nesting harvest at the time of my visit in March last.

The Island of Malagou, to the westward is similar to Culion, but it possesses the additional feature of a second line excavated by the waves about ten feet above the actual level. This seems to be the result of upheaval. Besides Malagou there are many small limestone islets, or mere pinnacles of grotesque shape. The seas are thus rendered peculiarly dangerous. The only port worthy of the name is Port Culion, with a town which is a mere cluster of Malay huts of bamboo and palm-leaves. The rocks are Palæozoic schists and quartzites. Thus we have a repetition of the formations as they occur in the Malayan Peninsula.

At Palawan and Mindanao the same formations are stated to occur. Of Mindanao there can be no doubt, but of Palawan little is known, and I have only seen the coast at a distance.

There is a continuance of the same geological features in South China, at least from those portions of the coast which I have seen between Macao and Swatow. At Hong Kong we have granite, ancient trap-rocks, felsites, and detached outliers of limestone exactly like the Palæozoic deposits all through the Eastern Archipelago. From the Canton River the same rocks have been seen by me together with well-marked Palæozoic fossils of carboniferous type (*Spirifer* especially).

I have never succeeded in getting away from the alluvial deposits of the great rivers of Cochin China. Just now the time could not be more unfavourable for any kind of exploration, but I believe the French are not neglecting the geology of the country.

Coal is extensively distributed in all the northern portions of the countries I have been describing. It is found in South China abundantly, Formosa, Tonquin, the Philippines, Japan, and Borneo, and I believe I have seen indications of a carbonaceous deposit in the Malay Peninsula.

Of the coals in South China little more is known than that they are abundant and of good quality. From the fossils I have seen they are probably of Palæozoic age. The Formosa coals are so bad that they have ceased to be worked or at least offered in the Hong Kong market. I know nothing of their age nor of the quality and age of the coals of Tonquin. The coals of the Philippines belong most probably to the Borneo older series. They are found on the south of Luzon and south of Zebu since 1827. More recently they have been found in the province of Albay (south-east of Manilla) and in Panay.

Samples from the latter mines were tried by the P. and O. Company with good results. The Japan coals are certainly Tertiary and most probably Miocene. Though brittle, they make such good steam coals that they are preferred to every other except Cardiff coal. Borneo is a mass of coal, and, as I believe, of very different ages. Those of Labuan were said to be Tertiary; those of Brunei look much older. But I question the Tertiary age of the Labuan beds.

The general character of the geology of the regions I have mentioned is (1) Granite rocks with older volcanic dykes; (2) Palæozoic schists and slates; (3) Limestones in detached outliers, probably of Carboniferous age; (4) Coal of various ages. There has been little upheaval, and that has revealed marine, Miocene, and Pliocene beds, with some few carbonaceous deposits.

J. E. TENISON-WOODS

Osaka, Japan, September 24, 1885

JOHN HUNTER'S HOUSE

EARL'S COURT HOUSE, once the residence of the illustrious John Hunter, has been made very properly the subject of a letter in the *Times* of Tuesday last, by Dr. Farquharson, M.P. The house, with which I have been familiar for the past twenty-two years, is well worth all the attention of the curious which Dr. Farquharson claims for it. It differs, no doubt, somewhat from what it was in Hunter's time, but not so much, I think, as my friend supposes; for a drawing I have had made of it, when compared with another drawing taken not long after Hunter's death, and now in the possession of the Royal College of Surgeons, shows no very important change. The Lions' Den, of which I have also had a faithful copy taken, is still in good preservation, and Mrs. Hunter's boudoir retains all its original character, as she, the accomplished authoress of the well-known song,—

"My mother bids me bind my hair,"—

had it herself decorated. The copper in which the Irish giant was boiled down is in good order, and stands in an outhouse in the same place in which it stood when the giant, in piecemeal, found his way into it. In 1850 the late distinguished scholar, Dr. Robert Willis, of Barnes, took me to Kensington to see a man who remembered John Hunter. He was the son of Hunter's gardener, and was ten years of age at the time of Hunter's death in 1793. This man related some curious anecdotes of the great anatomist. One of these had reference to his presence of mind. One day as Hunter was entering his garden by the field at the back, still a field, one of the lions had got loose from its den. From the house the people called out to Hunter to get out of the way into a place of safety. Instead of this he took his handkerchief from his pocket, and marching boldly up to the lion, flipped it back into the den, and securely shut it in.

That Hunter conducted dissections in this place is clear from the remains that have been dug up in the garden. I examined a number of bones that were thus unearthed by the late occupier during some improvements which were going on about fifteen years ago. The bones showed some sections and re-sections of so curious and skilful a kind, that I asked and obtained permission to retain a few of them.

Upon the death of John Hunter, Earl's Court, held for a time by Mrs. Hunter, and by more than one future occupier, was turned into an asylum for ladies under restraint for lunacy, was held for many years as that by the Misses Bonney, and got the general name of "Miss Bonney's House" or Asylum. In 1864 it passed, still as an asylum, into the possession of my late friend Dr. Gardner Hill, who played so great a part as the practical pioneer of the system of the treatment of the insane without restraint. Dr. Hill continued to reside in the house till his death, by apoplexy, a few years ago, and his family have held it since his death up to the close of the past year, when they left it on the expiration of their lease. The fate of the house will almost certainly be its absorption, with its grounds, into a square or a series of streets, so that nothing will remain of it beyond the views which I and others who are given to antiquarian research may have taken of it, and at my instance Mr. Gardner has added several views to his magnificent collection of London. The memory of the place is thus secured for the future at least. But I agree with my learned brother Farquharson that the copper ought to go to the Hunterian Museum, to join the giant who is already so conspicuous and famous there.

BENJAMIN WARD RICHARDSON

NOTES

AN American Pasteur Institute has been incorporated in New York, its declared objects being the study and treatment of rabies and diseases susceptible of inoculation.

THE Rev. Thomas John Main, formerly Fellow of St. John's College, Cambridge, and a chaplain in the Royal Navy, died on the 28th ult. Mr. Main took his Bachelor's degree at St. John's College in 1838, as Senior Wrangler and first Smith's Prizeman, and proceeded M.A. in due course. He was for a period of thirty-four years Professor of Mathematics at the Royal Naval College at Portsmouth. Mr. Main was the author of various works on the marine steam-engine.

THE death is announced from St. Petersburg of Prof. Zakharow, of the University there, an eminent Orientalist. Nearly thirty years ago he went to China as a Russian missionary, and after General Ignatieff's Treaty of Pekin in 1860, he was employed, on account of his knowledge of Chinese and Manchu, in the work of delimiting the frontier created by that treaty. He then prepared a large map of this region, of which only one copy has been made, which is at present in the Russian Topographical Department. He also compiled a Manchu-Russian dictionary, published in 1875, and a Chinese-Manchu-Russian dictionary was almost completed at the time of his death. On his return to Europe he was appointed Professor of Manchu in the University of St. Petersburg, and in addition to his dictionaries compiled also a grammar of that language, which is now dying out in China, as the Manchus are a mere handful in the midst of the Chinese Empire, and are gradually losing their special tongue. Manchu is, however, still used at Chinese Court ceremonials, and in officially addressing the Emperor of China in person. M. Zakharow's great works have therefore a special value.

THE Association for the Improvement of Geometrical Teaching will hold its annual general meeting on Friday, January 15, at 11.30 a.m., at University College, Gower Street. At the afternoon meeting (2 p.m.) the President (R. B. Hayward, F.R.S.) will give an address on the Correlation of the Different Branches of Elementary Mathematics. A discussion will follow the reading of the address. Persons interested in the objects of the Association or in the subject of the address are cordially invited to attend.

THE Prince of Wales having expressed his desire that specimens of Australian fish might be exhibited in the Aquarium which will be opened in connection with the forthcoming Indian and Colonial Exhibition, the Trustees of the Melbourne Exhibition Building have given the matter their consideration, with a view of determining if specimens of therarer varieties could be sent from the Melbourne Aquarium. It has, however, been found that very great cost would be incurred in sending anything like an adequate supply of fish, and the project has therefore been abandoned. It has been decided instead to forward for exhibition in the Victorian Court upwards of 100 water-colour drawings of the fishes of the colony, which have been executed to the order of the Trustees by a competent artist, and which, it is hoped, will be of interest to ichthyologists and others. It is also the intention of the Trustees to request the Government to assist them in the production of a descriptive work on Victorian fishes, the illustrations of which will be taken from these drawings. Prof. M'Coy has promised his assistance, and Mr. J. E. Sharrard, the Secretary to the Trustees, is already engaged in collecting materials for the work.

It is announced that the seventh Congress of Orientalists will be held at Vienna in September next. The sittings will take place in the lecture-hall of the new University. It is hoped that the Archduke Rénier will act as honorary president.

Among the additional lectures announced at the Society of Arts are:—"The Experiments with Lighthouse Illuminants at the South Foreland," by E. Price Edwards; "Magnetism of Ships and the Mariner's Compass," by Mr. W. Bottomley, jun.; "Photography and the Spectroscope in their Application to Chemical Analysis," by Prof. W. N. Hartley; "The Scientific Development of the Coal-Tar Industry," by Prof. R. Meldola.

Reports reached London on Tuesday that a severe shock of earthquake was felt on Monday morning at 10.20, all along the route between Dartmouth and Kingsbridge, Devonshire, as well as at other places lying more inland. Just after leaving Dartmouth the driver of an omnibus which runs daily to and from Kingsbridge experienced an oscillation of the ground, which lasted some seconds. On arriving at Stoke Fleming a number of persons stated that they felt the shock. A house at Stokepenny is stated to have "rocked." In the "Green Dragon" public-house the shock caused a quantity of plaster to fall down from the ceilings. At Street the oscillation was similarly felt. At Blackawton the shock is reported to have been very conspicuously felt. It appears, however, to have been most severe at Torcross. The occupants of the "Fisherman's Arms" public-house, which stands on the beach, were so frightened that they rushed out of the place, thinking, as they said, that the building was going to fall. Mr. T. R. Vickary, of the Torcross Hotel, gives several particulars of the severity of the shock. It appears to have been felt by almost every one in the village. At Stoneham, Chillington, and Frogmore the oscillation was also experienced.

A slight shock of earthquake, lasting seven seconds, was felt in Venice at 11 o'clock on the night of the 29th ult. No damage was done.

The volcano of Colima, on the Pacific coast of Mexico, exhibited a violent eruption on the 27th ult., which caused great alarm. The streams of lava completely covered the sides of the mountain. At the date of the last report flames were still darting from the crater, and clouds of smoke overhung the summit.

Mr. Blanford's theory of the winter rains of Northern India, based on a study of the meteorological registers, is as follows:—We have, he says, in the first instance, steady evaporation over an extensive moderately humid tract, at a comparatively low temperature, it is true, but in an atmosphere the stillness of which allows of the steady diffusion of the vapour to high levels, and the consequent formation of cloud. The slight disturbance of the baric equilibrium which follows (since the vertical decrease of temperature in a cloud-laden atmosphere is slower than in a clear atmosphere) is succeeded by a gentle indraught of warmer and more humid air from the south; for the Himalaya bars access to northerly winds. A vortex is then rapidly formed, accompanied with an increased cloud-formation, and speedily followed by precipitation, which takes the form of snow on the hills, and of rain over the river plains. The rainfall is invariably followed by a cool wind, and a wave of high barometric pressure from the west, which Mr. Blanford attributes to a drainage of cool heavy air from the valleys of the hills surrounding the Punjaub and the high lands of Beloochistan and Afghanistan—air cooled by precipitation on the mountains. If this theory be correct, the stillness of the atmosphere, combined with the presence of a moderate evaporation, must be accepted as the condition which primarily determines the formation of barometric minima and the winter rains of Northern India. As this stillness is due to the presence of lofty mountain-ranges in the north, it follows that, if the Himalayan chain were absent, these rains would probably cease, for any local evaporation in the Punjaub and the valley of the Ganges would be swept away by strong dry north-east winds blowing from the seat of high pressure, which in the winter months lies in Central Asia.

The electric lighting of the French Opera House is almost complete. The number of incandescent lights is 3000.

M. Joubert, the director of the Trocadéro popular Observatory, has made arrangements with the several telegraphic stations in Paris, so that the public may be warned when the sky is deemed sufficiently clear for conducting observations and demonstrations.

Messrs. Swan Sonnenschein and Co. announce for early publication a Pocket Handbook to the Flora of the Alps, specially adapted for botanical tourists, and edited by Mr. A. W. Bennett.

According to the Report for the past year of the Superintendent of the Royal Botanic Garden at Calcutta, further attempts to introduce into Bengal the kind of plantain (*Musa textilis*) from which Manilla hemp is derived have proved failures, owing to the low temperature of the cold weather; but the plant (*Sanseviera Zeylanica*) from which bow-string hemp is obtained grows very well. The Japan paper-mulberry, which has lately been introduced, has also been a success. Efforts are being made to introduce other plants of economic value, the principal being the coca plant, from which the important alkaloid cocaine is derived. The additions to the herbarium during the year appear to have been unusually large and comprehensive. As an example of the public utility of the Garden, it may be mentioned that 23,433 living plants were distributed to public institutions in India, while those sent abroad were proportionally numerous. In the same way 2,979 packets of seeds were sent out. The Report of the Lloyd Botanic Garden in Darjeeling is also included in the paper, which concludes with the usual statistical returns. We are glad to notice at the end a copy of a resolution conveying the thanks of the Lieutenant-Governor of Bengal to those concerned in administering the Gardens.

We have received the numbers of the *Journal* of the Asiatic Society of Bengal (Science Section) for 1885, so far as they have been published. They contain in all eleven papers, some being continuations of papers previously published. Mr. Lionel de Nicéville contributes a fourth list of butterflies taken at Sikkim in October 1884, with notes. The number of species already recorded was 284, which is now raised to 313, or about twice the number of species found throughout the year in Calcutta; but even this number does not exhaust the region, for some valleys and the higher elevations were not explored. The same writer describes some new Indian *Rhopalocera*, and also a list of the butterflies of Calcutta and its neighbourhood, with notes on their habits, food-plants, &c. Mr. Atkinson publishes the second and third instalment of his notes on Indian

Rhynchota. Dr. Giles, the Surgeon-Naturalist to the Indian Marine Survey, writes on the structure and habits of *Cyrtophium calamicola*, a new tubicolous amphipod from the Bay of Bengal, a description of a new species of the amphipod genus *Melita* from the same place, and notes on Prothallus of *Padina pavonia.* These three form part of the Natural History Notes of the Indian Marine Survey steamer *Investigator.* Commander Alfred Carpenter, of the same steamer, under the title "The Swatch of no Ground," explains the presence in the deltaic banks ("the-Swatch") off the mouths of the Ganges and the Brahmaputra of channels of great depth. Mr. Hill, the Meteorological Reporter to the North-Western Provinces and Oudh, contributes observations on the solar thermometer at Lucknow, while last of all comes a paper from Japan. Dr. O. F. von Möllendorff (not to be confounded with his brother of recent Corean fame) writes on Japanese land- and freshwater-mollusks, a series of notes based chiefly on a collection made by Dr. John Anderson during the year 1884, and sent to the writer for classification.

WE are glad to learn that Prof. Morse, Director of the Peabody Academy of Science, has in the press a work entitled "Japanese Homes and their Surroundings." Prof. Morse, it may be remembered, was Professor of Zoology in the University of Tokio, and his prehistoric discoveries in Japan formed one of the earliest of the publications of that institution. The publishers of the work, which will contain numerous illustrations by the author, are Messrs. Ticknor and Co. of Boston.

AT a meeting of the Seismological Society of Tokio held on November 18, 1885, in the University there, Prof. Shida described an instrument which he had designed to give an automatic record of earth-currents. The chief feature in it is an ingenious method of obtaining a record of the position of the coil or needle which indicated the current which might be passing through the instrument. This was accomplished by the needle, as it turned, making a series of almost frictionless electrical contacts between a series of metallic points and a film of liquid. The instrument has been practically worked, and is said to have yielded satisfactory records. A second paper by the same writer gave a history of all the facts with which we are acquainted respecting the phenomena of earth-currents. A considerable portion of the material embodied in the paper was derived from Prof. Shida's own observations on the lines and cables of this country. He made numerous references to instances where earth-currents of unusual magnitude had accompanied or preceded earthquakes. Many theories have been advanced to account for these phenomena, and it has been demonstrated by several investigations that they have a connection with the occurrence of sunspots. In the discussion which followed, Prof. Knott referred to the possibility of these disturbances being due to the inductive action of electrified bodies of air, while Prof. Milne added to the instances adduced by Prof. Shida of the simultaneous occurrence of earthquakes and earth-currents. Earthquakes occurring in America have, by the currents which had accompanied them, recorded themselves in Europe.

THE Japanese do not appear to have lost any of their faith in the efficacy of vaccination for the small-pox. They have just enacted a very stringent law on the subject, for, besides ordinary vaccination in the first year of infancy, it provides for at least two subsequent re-vaccinations at intervals of from five to seven years, so that by the time a child has reached its fifteenth year it will have been vaccinated three times. Besides, during epidemics of small-pox, local authorities have power, when they deem it necessary, to order the vaccination of all the inhabitants of their districts, irrespective of the vaccinations required by the law.

WE are informed that it is not the case that Dr. Sklarek has arranged to edit a new scientific journal to be published in Brunswick.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. T. W. Hall; a Sooty Mangabey (*Cercocebus fuliginosus* ♀) from West Africa, presented by Mr. T. Riseby Griffith; a Common Badger (*Meles taxus*), British, presented by Mr. Charles E. Russell; a Siamese Blue Pie (*Urocissa magnirostris*) from Siam, a Chinese Jay Thrush (*Garrulus chinensis*) from China, a Brazilian Hangnest (*Icterus jamaicai*) from Brazil, presented by Mr. Charles Clifton, F.Z.S.; an Alexandrine Parrakeet (*Palæornis alexandri*) from India, presented by Mr. C. Kerry Nicholls, F.Z.S.; a Ring-necked Parrakeet (*Palæornis torquatus*) from India, presented by Miss Shackthwaite; a Larger Hill-Mynah (*Gracula intermedia*) from India, presented by Miss G. Lampard; a Greater Spotted Woodpecker (*Dendrocopus major*), British, presented by Mr. A. S. Hutchinson; a Scops Owl (*Scops giu*), British, presented by Mr. J. H. Leech, F.Z.S.; a Caracal (*Felis caracal*), a Puff Adder (*Vipera arietans*), three Horned Vipers (*Vipera cornuta*), an African Cobra (*Naia haje*), a Hyghian Snake (*Elaps hygiæ*), a Smooth-bellied Snake (*Homolosoma lutrix*), two Rhomb-marked Snakes (*Psammophylax rhombeatus*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; twelve Quails (*Coturnix communis*) from South Africa, presented by Capt. M. P. Webster; a Leopard (*Felis pardus*) from India, five Mauge's Dasyures (*Dasyurus maugæi*), a White-backed Piping Crow (*Gymnorhina leuconota*) from Australia, deposited; a Virginian Opossum (*Didelphys virginiana*) from North America, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

DISCOVERY OF A NEW NEBULA BY PHOTOGRAPHY.—MM. Paul and Prosper Henry have recently announced the discovery by means of photography of a new nebula in the Pleiades. It was first photographed on November 16 last, and, though it was again photographed on December 8 and 9, MM. Henry have as yet been unable to detect it by direct telescopic observation. The nebula is about 3′ in extent, and "très-intense." It presents a well-marked spiral form, and seems just to escape Maia. Its position is as follows:—R.A. 3h. 38m. 57s., Decl. 24° 1′ N.

GORE'S NOVA ORIONIS.—M. C. Wolf, who has examined the spectrum of this star, finds that the impression of the presence of bright lines which a first glance produces is not confirmed when the spectrum is more carefully examined under a high dispersion. The spectrum is simply that of the well-known third type, viz. a continuous spectrum crossed by a succession of bands, which terminate towards the violet in a very dark and sharp edge, and which gradually shade away towards the red. M. Wolf further believes that he was able, in the moments of best definition, to resolve the dark bands into lines. The Nova therefore does not appear to resemble the so-called "temporary" stars, but to be simply a variable of the same class as Mira Ceti. Prof. Millosevich gives its exact position for 1885·0 as follows:—R.A. 5h. 48m. 59·59s., Decl. 20° 9′ 13″·2 N.; or 1m. 25·21s. *f* and 5′ 59″·14 *s* of χ' Cygni. It is almost precisely due north of α Orionis, and distant from it 12° 46′ 20″.

THE ASTRONOMICAL PRIZES OF THE PARIS ACADEMY OF SCIENCES.—The Lalande Prize of the Académie des Sciences has been decreed to M. Thollon for his great map of the solar spectrum. This map, which has so far demanded four years of uninterrupted work, extends from *A* to *b*, and contains 3200 lines, 900 of which M. Thollon has been able to identify as of telluric origin. The Damoiseau Prize is reserved, no memoir having been offered for it. The subject proposed is the same as in former years: a revision of the theory of the satellites of Jupiter; a discussion of observations with special reference to the direct determination of the velocity of light; and lastly, the construction of particular tables for each satellite. The Valz Prize has been awarded to Dr. Spörer for his researches on sun-spots,—his discovery of the striking relationship between the distribution of the spots in latitude and the epochs of their maxima and minima receiving especial notice.

FABRY'S COMET.—The following ephemeris from elements he has recently computed is given by Dr. S. Oppenheim in the *Astr. Nach.*, No. 2702:—

Ephemeris for Berlin Midnight

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 JANUARY 10-16

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 10

Sun rises, 8h. 5m.; souths, 12h. 7m. 51·1s.; sets, 16h. 11m.; decl. on meridian, 21° 55′ S.: Sidereal Time at Sunset, 23h. 31m.

Moon (at First Quarter on Jan. 13) rises, 10h. 17m.; souths, 15h. 56m.; sets, 21h. 45m.; decl. on meridian, 4° 41′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 25	10 27	14 29	22 0 S.
Venus	9 41	14 55	20 9	9 43 S.
Mars	21 53*	4 24	10 55	5 21 N.
Jupiter	23 7*	5 5	11 3	1 5 S.
Saturn	14 44	22 54	7 4*	22 35 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Meteor Showers

The cloudy weather generally prevailing at this season of the year greatly interferes with meteor-observation, but a number of fairly active radiants have been observed, the following amongst others:—From the constellation of the Lynx, R.A. 104°, Decl. 53° N.; from Coma Beren, R.A. 181°, Decl. 35° N.; from near χ Cygni, R.A. 295°, Decl. 53° N. Large meteors should be looked for on January 15, 16, and 17.

STANDARDS OF WHITE LIGHT[1]

THE experimental work of the Committee during the past year has not been extensive, as they had no funds at their disposal for experimental research, and they have been chiefly occupied with reviewing what has been done in the past and laying plans for future operations.

Lord Rayleigh has constructed an instrument which he calls a monochromatic telescope, by means of which the illuminated screens of a photometer may be examined, allowing light only of one definite colour to pass. It was hoped by Lord Rayleigh that experiment might show that, with some suitably-chosen colour, this instrument, used with any ordinary photometer, would, in comparing lights of different intensities and temperatures, give to each a candle-power which would be sufficiently accurate to represent for commercial purposes the intensity of the light. The Secretary has made some experiments at the Society of Arts, where he was kindly permitted to use the secondary batteries and glow-lamps; but the results so far are not definite enough to justify their publication.

Mr. Vernon Harcourt has been engaged on an investigation on the barometrical correction to his pentane standard, and on another concerning the possibility of using lamp-shades as a protection from air-currents. His researches are communicated independently to the meeting.

Capt. Abney and Col. Festing have continued their observations on the intensity of radiations of different wave-lengths from incandescent carbon and platinum filaments at different

[1] Report of the Committee, consisting of Prof. G. Forbes, Capt. Abney, Dr. J. Hopkinson, Prof. W. G. Adams, Prof. G. C. Foster, Lord Rayleigh, Mr. Preece, Prof. Schuster, Prof. Dewar, Mr. A. Vernon Harcourt, and Prof. Ayrton, appointed for the purpose of reporting on Standards of White Light. Drawn up by Prof. G. Forbes (Secretary).

temperatures, which will go far to assist the Committee in their work.

Other isolated experiments have been made by members of the Committee, which will be published in due course.

Most of the members have examined the experiments of the Trinity Board at the South Foreland.

Existing Standards.—A consideration of existing standards convinces the Committee that the standard candle, as defined by Act of Parliament, is not in any sense of the word a standard. The French "bec Carcel" is also liable to variations; and with regard to the molten platinum standard of Violle, it seems that the difficulty of applying it is so great as to render its general adoption almost impossible.

With regard to the so-called standard candle, the spermaceti employed is not a definite chemical substance, and is mixed with other materials, and the constitution of the wick is not sufficiently well defined. Hence it is notorious that interested parties may prepare candles conforming to the definitions of the Act which shall favour either the producer or consumer to a serious extent. In view of these defects of the standard candle, it is a matter of great importance that a standard of light should be chosen which is more certain in its indications.

The Committee have looked into the merits of different proposed standards, and the majority feel satisfied that, for all the present commercial requirements, the pentane standard of Mr. Vernon Harcourt—since it has no wick and consumes a material of definite chemical composition—when properly defined, is an accurate and convenient standard, and gives more accurately than the so-called standard candle an illumination equal to that which was intended when the Act was framed.

Yet the Committee, while desiring to impress the Board of Trade and the public with these views, do not feel inclined at present to recommend the adoption of any standard for universal adoption until, further information on radiation having been obtained from experiment, they may learn whether or not it may be possible to propose an absolute standard, founded, like electrical and other standards, on fundamental units of measurement—a standard which, for these reasons, would be acceptable to all civilised nations. They are, however, inclined to look upon the pentane lamp as an accurate means of obtaining an illumination to replace the so-called standard candle.

Proposed Experimental Researches.—Radiation is measured as a rate of doing work, and consequently radiation might be measured in watts. The illumination (or luminous effect of radiation) depends partly upon the eye, and is a certain function of the total radiation. This function depends upon the wave-length of the radiation, or on the different wave-lengths of which the radiation, if it be compound, is composed. This function of the radiation perceived by the eye is partly subjective, and varies with radiations of different wave-lengths and with different eyes. Thus the illumination cannot, like the radiation, be expressed directly in absolute measurement. But the connection between the illumination and the radiation can be determined from a large number of experiments with a large number of eyes, so as to get the value of the function for the normal human eye. This function, however, is constant only for one source of light, or, it may be, for sources of light of the same temperature. It appears, then, that, in the first instance at least, a standard should be defined as being made of a definite material at a special temperature.

The energy required to produce a certain radiation in the case of a thin filament of carbon or platinum-iridium heated by the passage of an electric current can be easily measured by the ordinary electric methods, and the radiation may be measured by a thermopile or a bolometer, which itself can be standardised by measuring the radiation from a definite surface at 100° C., compared with the same at 0° C. The electric method measures the absorption of energy; the thermopile measures the total radiation. These two are identical if no energy is wasted in convection within the glass bulb of the lamp, by reflection and absorption of the glass, and by conduction from the terminals of the filament. Capt. Abney and Col. Festing have come to the conclusion that there is no sensible loss from these causes. The Committee propose to investigate this further. This constitutes a first research.

No research is necessary to prove that with a constant temperature of a given filament the luminosity is proportional to the radiation, because each of these depends only upon the amount of surface of the radiating filament. It will be necessary, however, to examine whether with different filaments it be possible to maintain them at such temperatures as shall make the illumination of each proportional to the radiation. This will be the case if spectrum curves, giving the intensity o radiation in terms of the wave-length when made out for the different sources of light, are of the same form. Thus a second research must be undertaken to discover whether the infinite number of spectrum radiation curves, which can be obtained from a carbon filament by varying the current, are identical in form when the filament is changed, but the material remains so far as possible of constant composition.

It will be an object for a later research to determine whether, when the radiation spectrum curve of any source of light has been mapped, a similar curve can be found among the infinite number of curves which can be obtained from a single filament.

The next step proposed is to examine a large number of carbon or of platinum-iridium filaments, and to find whether the radiation spectrum curve of different specimens of the same material is identical when the resistance is changed in all to x times the resistance at 0° C. If this law be true, a measurement of the resistance of the filament would be a convenient statement of the nature of the radiation curve. If, then, a number of filaments were thus tested to give the same radiation spectrum curve, their luminosities would in all cases be proportional to their radiations, or (if there be no loss in convection, conduction, absorption, and reflection) proportional to the electrical energies consumed.

Thus it might be hoped to establish a standard of white light, and to define it somewhat in the following manner:—*A unit of light is obtained from a straight carbon filament, in the direction at right angles to the middle of the filament, when the resistance of the filament is one-half of its resistance at* 0° *C., and when it consumes* 10^9 *C.G.S. units of electrical energy per second.*

Since Mr. Swan has taught us how to make carbon filaments of constant section by passing the material of which they are composed through a die, it is conceivable that another absolute standard should be possible—viz., a carbon filament of circular section, with a surface, say, 1-100th sq. cm., and consuming, say, 10^9 C.G.S. units of energy per second.

Whether such standards are possible or not depends upon the experiments of the Committee. The probability of success is sufficient to render these experiments desirable.

Proposed Later Experimental Researches.—Should these hopes be realised, and an absolute standard of white light thus obtained of a character which would commend it to the civilised world, it would then become an object of the Committee to find the ratio of luminosity when the radiation spectrum curve of the standard filament is varied by varying the current, and consequently the resistance of the filament.

Thus, by a large number of subjective experiments on human eyes, a multiplier would be found to express the illumination from the standard lamp, with each degree of resistance of the filament.

A research, previously hinted at, would then be undertaken—viz., to find whether the radiation spectrum curves of all sources of illumination agree with one or other of the curves of the standard filament. It is not improbable that this should be the case except for the high temperature of the electric arc.

Should this be found to be true, then photometry would be very accurate, and the process would be as follows:—*Adjust the standard filament until its radiation spectrum curve is similar to that of the light to be compared.* (This would probably be best done by observing the wave-length of the maximum radiation, or by observing equal altitudes on either side of the maximum, the instruments used being a spectroscope and a line thermopile or a bolometer.) The total radiation of each is then measured at equal distances by the thermopile. The resistance of the filament is measured, and its intensity in terms of the unit of white light obtained therefrom by the previous research. The luminosity of the compared source of light is then obtained directly.

The Committee desire to be reappointed, and to enable them to carry out the researches indicated they ask for a grant of 30*l.*

PHYSICS AT JOHNS HOPKINS[1]

THE large and well appointed laboratories recently erected by the Trustees of the Johns Hopkins University for the Chemical and Biological Departments have by contrast made

[1] From *Science* of December 18, 1885.

the more evident the needs of the Physical Department, which has been obliged to occupy temporarily parts of four different buildings. The Trustees, recognising this need, are now erecting a building for a physical laboratory. The new laboratory is to be a handsome building of red brick, trimmed with brown sandstone, and will occupy a fine site about a block from the other University buildings, on the corner of a quiet little street midway between the more important streets, which carry the bulk of the traffic of that region. It will therefore be as free from disturbance from the earth-vibrations as could be expected in a city.

The building will be 115 feet long by 70 feet broad, and will have four stories besides the basement. In the centre of the building, and below the basement, are several vaults for instruments requiring to be used at constant temperature, also a fireproof vault for storage. In these vaults will be placed Prof. Rowland's dividing-engine, by which the diffraction-gratings are ruled, and the Rogers-Bond comparator, which has recently become the property of the University. In the basement will be rooms for the mechanical workshop, for furnaces, and for piers for instruments requiring great stability. The first floor will include the main lecture-room, which will accommodate 150 persons, and rooms for investigations by advanced students in heat and electricity. The second floor will contain mathematical lecture-rooms, studies for instructors, and a room for the mathematical and physical library of the University.

The elementary laboratory will be on the third floor, which will also have rooms for more advanced work. The fourth floor will contain rooms for special work in light.

There will be a tower on the south-east corner of the building, which will have two rooms above the fourth floor. The upper of these will be provided with telescope and dome, and will be a convenient observatory when great steadiness in the instruments is not required. There will be power in the building for driving the machinery in the workshop and for running the dynamo-machines. A large section of the building is to be made entirely free from iron. The sash-weights will be of lead, and the gas-pipes of brass. Brackets will be attached to the walls, on which galvanometers and cathetometers may be placed. In order to avoid the inconvenience of having piers go up through the lower rooms, and yet to secure steadiness, beams have been introduced into the floors, which reach from one wall to the other between the regular floor-beams, and do not touch the floor at any point. If, now, a table is made to rest on two of these beams, by making holes in the floor over them to admit the legs of the table, it is entirely undisturbed by any one walking over the floor, except by such motion as is transmitted to the walls. There will also be a small vertical shaft in the wall of the tower, running from top to bottom, in which a mercurial manometer may be set up.

The vaults for constant temperature have been built with double walls, so that a current of air may be drawn between them whenever desirable to prevent dampness. It is expected that the laboratory will be ready by October next.

The photographic map of the spectrum upon which Prof. Rowland has expended so much hard work during the past three years, is nearly ready for publication. The map is issued in a series of seven plates, covering the region from wave-length 3100 to 5790. Each plate is 3 feet long and 1 foot wide, and contains two strips of the spectrum, except Plate No. 2, which contains three. Most of the plates are on a scale three times that of Angström's map, and in definition are more than equal to any map yet published, at least to wave-length 5325. The 1474 line is widely double, as also are b_3 and b_4, while E may be recognised as double by the expert. In the region of the H line these photographs show even more than Lockyer's map of that region. Negatives have also been prepared down to and including the B group, and they may be made ready for publication, one of which shows eleven lines between the D lines. A scale of wave-lengths is printed on each plate, and in no case does the error due to displacement of the scale amount to one part in 50,000. The wave-lengths of over 200 lines have been determined to within one part in 500,000, and these serve as reference lines to correct any small error in the adjustment of the scale. The great value of such a map lies not only in the fact that it gives greater detail and is more exact than any other map in existence, but that it actually represents the real appearance of the spectrum in giving the relative intensities and shading of groups of lines, so that they are readily recognisable. The photographs were taken with a concave grating 6 inches in diameter, and having a radius of curvature of $21\frac{1}{2}$ feet, and the photographs were taken when the plate was placed directly opposite the grating; both the sensitive plate and grating being perpendicular to a line joining their centres, and placed at a distance apart equal to the radius of curvature of the grating, the slit being on the circumference of the circle, whose diameter is the distance between the grating and plate. With this arrangement, the spectrum is photographed normal for wave-lengths without the intervention of any telescopes or lens systems; and a suitable scale of equal parts applied to such a photograph at once gives relative wave-lengths.

Few persons have any idea of the perseverance and patience required to bring such a task to a successful issue. More than a year was devoted to preliminary experiments designed to discover the best mode of preparing the plates for the particular regions to be photographed. Hundreds of preparations were tested to find their influence on the sensitised plate, and the whole literature of photography was ransacked, and every method tested to the utmost, before the work of taking the negatives could begin.

The Rogers-Bond comparator, which has been already referred to as having been purchased by the University lately, is one of two instruments that were constructed in 1881 by Pratt and Whitney of Hartford, Conn. The general plan and requirements were made out by Prof. W. A. Rogers of Cambridge, and the drawings and details were worked out by Mr. George M. Bond, then a student at Stevens Institute. The comparator was designed for making exact comparisons of standards of length. The other similar comparator is owned by the Pratt and Whitney Manufacturing Company, and is used by them in testing and constructing their standard gauges.

The instrument consists essentially of two microscope-carriages, which slide on two parallel cylindrical steel ways between stops, which may be clamped at any point. A carriage entirely independent of the ways on which the microscopes slide supports the two bars to be compared, and is provided with means of accurate and rapid adjustment, by which the bars may be successively brought into position under the microscopes, and the lengths compared by the micrometers attached to the microscopes; or one microscope only need be used, and slid first against the stop at one end, and then against that at the other end. The instrument also affords great facility in determining fractions of a given length with any desired degree of precision. The instrument is one requiring the utmost skill in its construction, and it cost several thousand dollars to make it. A full account of this remarkable instrument is given in the *Proceedings* of the American Academy of Arts and Sciences for 1882–83.

K.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Chancellor of St. Andrew's University (His Grace the Duke of Argyll) has given his sanction to a recent enactment of the University Court empowering the Senatus to admit to the Science Degrees of the University, students who may have received their education at University College, Dundee.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 17, 1885.—"A Preliminary Account of a Research into the Nature of the Venom of the Indian Cobra (*Naja tripudians*)." By R. Norris Wolfenden, M.D., Cantab. (from the Physiological Laboratory, University Coll., London). Communicated by E. A. Schäfer, F.R.S.

In this account the author refers only to cobra venom, the venom of *Naja tripudians*. The dried venom dissolved in water and filtered from accidental particles yields a solution, clear, and usually slightly acid. This solution contains a large amount of proteïd. Boiling produces a copious coagulum, and after removal of all coagulum by frequent filtration there is still much proteïd in the solution. A fresh solution of the venom is at once precipitated by neutral salts such as $MgSo_4$, NaCl, &c., and also by absolute alcohol.

The previous valuable labours of Sir Joseph Fayrer (*Proc. Roy. Soc.*, 1873, 1874, 1875, 1878), and Dr. Lauder Brunton and others, have dealt chiefly with the physiological side of the question, but have left the chemical nature of these snake venoms still undetermined.

Weir Mitchell and Reichert (*Med. News*, April 28, 1883; *Lancet*, July 21, 1883), working with the venoms of American snakes, have indicated in these venoms certain poisonous proteïds, the nature of which, however, is not fully elucidated. Wall's ("Indian Snake Poisons," Allen and Co., 1883) experiments and conclusions lead to the same view. Blyth (*The Analyst*, vol. i.) attributed the venom to an acid ("cobric acid") of deadly power. Gautier asserted that he had separated two ptomaïnes from Trigonocephalus and Naja venom. The author undertook this research with the object of determining whether the active venomous properties reside in the proteïd constituents or some other non-proteïd body or bodies. His work falls under the following heads:—

(1) The possibility of cobra-poisoning being due to "germs" or living organisms in the secretion.
(2) Its possible dependence upon an alkaloidal body.
(3) Its dependence upon some acid (cobric acid).
(4) Its dependence upon the proteids contained in it.
(5) The mode of action of these proteïds.

With regard to the first proposition, the author finds nothing in cobra poison which will grow under cultivation methods favourable for such organisms. The symptoms of the poisoning are entirely unlike bacillary infection, and resemble more the effect of some rapidly-acting chemical poison. With regard to the presence of "alkaloids" in cobra venom, the author made three examinations of the dried venom by the Stass Otto method, but failed to find any trace of an alkaloid. He thus confirms the results of Prof. Wolcott Gibbs, who examined cobra poison for Dr. Weir Mitchell, in search of "ptomaines," but stated that he could find no trace of such bodies. In reference to the "cobric acid" said to have been obtained by Blyth from cobra venom, the author remarks that as it is said to be crystalline, it will presumably readily dialyse. Searching the dialysates for such a body, the author has failed to meet with it. Dialysates that retain any toxic power do so by virtue of the proteid which they contain, since cobra venom, or the dialysate of cobra venom, loses its poisonous properties with the removal of its proteids.

The fourth proposition—viz. that the toxic power of the venom is resident in the proteïds, is the author's chief point, and on this subject he remarks as follows:—

The coagulum obtained by boiling the venom is harmless when injected into rats. The filtrate from the coagulum is toxic, though in less degree than the original solution. The author thinks this toxic power to be due to syntonin remaining in the solution. That it is due to proteïd is shown by the fact that, with the removal of this proteïd by acetate of lead, it is rendered harmless.

The dialysates of cobra venom which are toxic contain proteïd, but lose their poisonous properties when this proteïd is removed by boiling with ferric acetate.

The variable degree of toxic power of the dialysates is dependent on the length of time the dialysis has lasted, and thus upon the amount of proteïd that has passed through the dialyser.

From what has been said as to the non-existence of any poisonous acid or alkaloid in cobra venom, and also the diminution of toxicity on boiling solutions of the venom, and complete removal of poisonous properties on completely freeing the boiled venom from such proteid as has escaped coagulation by heat, and, further, as to the dependence of the toxicity of the dialysates upon the proteïd therein, there can be no further doubt that the toxic power of the venom is entirely due to its proteïds, and that it completely loses all poisonous power on the removal of these bodies.

The formerly reputed power of permanganate of potash as an antidote is explained by the action of this body upon albumens, which it converts into oxyprotosulphonic and other allied acids (according to Brücke and Maly) and it fails as an antidote within the body because it oxidises all albumens indifferently, without any selective power for the cobra proteïds.

The proteïds contained in cobra venom are—

(1) Globulin, which is obtained by saturation and shaking with $MgSo_4$, and which is coagulated in its solutions at 75° C. It is extremely toxic, and kills by involving the respiratory system, producing speedy asphyxia.

(2) Serum albumen, present in the filtrate from the $MgSo_4$ precipitate, and which is brought down on further saturation and shaking with Na_2So_4. It coagulates between 70° and 80° C. There is very little of it present, and it probably acts in a poisonous manner by producing a general and ascending paralysis.

(3) Syntonin, which is left in the filtrate after boiling the venom, and is also partially precipitated by $MgSo_4$, along with the globulin, and also appears in the dialysates, from which it is entirely removed by boiling with ferric acetate, or lead acetate. It possesses poisonous properties, chiefly like the globulin.

It is possible that some specimens of cobra venom contain a little peptone, though it can only be in faint traces. The bodies which Weir Mitchell and Reichert have described as peptone in Crotalus and Mocassin venoms are probably albumoses. That they are precipitated by dilute acetic acid, NaCl, and liquor potassa indicates this character. The "globulin," which they have described as dissolved by heating instead of coagulating, is also possibly a body of this nature. The complete removal of all proteids from cobra poison by boiling with ferric acetate, except in some specimens the very faintest trace (as indicated by metatungstic acid), shows that when peptone is present it is only in the smallest traces, and it is not constantly found in cobra venom.

In conclusion, the author desires to express his thanks to the Indian executive for readily acceding to the request of Mr. Vincent Richards, a member of the last Snake Commission, to supply him with the dried venom. The amounts received have, however, been small, making the research not only slow, but very difficult.

Victoria (Philosophical) Institute, January 4.—A paper by Mr. Boscawen, on the Abramic Migration, and the light thrown thereon by recently discovered Assyrian Inscriptions was read.

PARIS

Academy of Sciences, December 28, 1885.—M. Jurien de la Gravière, Vice-President, in the chair.—Obituary notice of the late M. L. R. Tulasne and his botanical work, by M. P. Duchartre.—Note on the new star in Orion recently discovered at Lord Crawford's Observatory, Dun Echt, by M. C. Wolf. From a study of its spectrum, which belongs to Class III., section *a* of Vogel, this would appear to be, not a temporary star like τ Coronæ discovered in 1866, but a true star hitherto undetected.—On the movement of the molecules of the "solitary wave," by M. de Saint-Venant.—Researches on the functions of Wrisberg's nerve—complementary note, by M. Vulpian.—Researches on the real origin of the secreting nerves of Nuck's salivary gland, and of the labial salivary glands of the dog, by M. Vulpian.—Observations on the structure of the vascular system in the genus Davallia, and particularly in *Davallia repens*, by M. A. Trécul.—On the respiration of plants outside the living organisms, in connection with M. Regnard's recent communication, by M. Ad. Chatin.—On a new theory of algebraic forms (continued), by Prof. Sylvester.—Report on M. Mestre's claim of priority of discovery in connection with MM. Napoli and Abdank-Abakanowicz's integraph, by the Commissioners, MM. Bertrand and Jordan. To a certain extent M. Mestre's claim is allowed; he appears entitled to the credit of the general idea of the apparatus, all the details of which must, however, be accredited to M. Napoli.—Letter on the proposed appointment of a special Commission to study the subsidence of the land along the coasts of the English Channel, by the Minister of Public Instruction.—On the relative frequency of the spots on the two hemispheres of the sun, by M. Spörer. Between the years 1880-82 the spots occurred most frequently in the northern hemisphere (56 per cent.), but from 1882-85 they were most frequent in the southern, being last year in the proportion of 69 to 30 per cent.—On a unique method of determining the constants of the altazimuth, and of M. Lœwy's recently-invented meridian lunette "à grand champ," by M. Gruey.—Observations of Barnard's comet made at the Observatory of Bordeaux, by MM. G. Rayet, Doublet, and Flamme.—Observations of Fabry's comet made at the Observatory of Bordeaux, by MM. G. Rayet and Flamme.—Elements of Fabry's comet, by M. Gonnessiat.—Note on the secular diminution of the obliquity of the ecliptic, by M. F. Folie.—On the potential energy of two ellipsoids mutually attracting each other, by M. O. Callandreau.—On the doubly periodical functions of the third species, by M. Appell.—Note on the effects of the rheostatic machine of quantity (two illustrations), by M. Gaston Planté.—A new application of the principle determining the transmission of power to a distance by means of electricity, by M. Manceron.—Application of the numerical laws of the chemical equilibria to the dissociation of the hydrate of chloride, by M. H. Le Chatelier. The principles here developed are directly applicable to all the hydrates of gaseous bodies, and to a large number of other compounds, such as the alkaline bi-carbonates, with which the author is at present occupied.—Action of some deoxidising agents on vanadic acids, by M. A. Ditté. It is shown that, when subjected at a high temperature to the action of hydrogen, sulphur, arsenic, phosphorus, and some other reducing agents, vanadic acid may, according to the circumstances, lose a greater or less quantity of oxygen.—Note on the preparation and physical properties of the pentafluoride of phosphorus, by M. H. Moissan.—Note on the combinations of the trichloride of gold with the tetrachlorides of sulphur and selenium, by M. L. Lindet.—Thermic researches on glyoxylic acid ($C_4H_4O_8$), by M. de Forcrand.—On the oxidation of sebacic acid, by M. H. Carette.—On a new means of testing the purity of volatile substances, by M. E. Duclaux.—On the normal character of the morbid process developed by tuberculous inoculations, by M. G. Colin.—Remarks on the character of the glycogen observed in the ciliated Infusoria, showing that it is in every respect analogous to that developed in the liver of higher organisms, by M. E. Maupas.—A physiological study of acetiphenone, by MM. A. Mairet and Combemale.—On the dialytic properties of the membrane of the cyst in *Vorticella nebulifera* and other Infusoria, by M. F. Fabre.—Note on the polychete Annelidæ found on the French coast, district of Dinard, by M. de Saint-Joseph.—On the traces left by the Quaternary glaciers in the cave of Lombrives, Ariège Valley, by M. E. Trutat.—Remarks on the first sheets of the new geological map of France, prepared to a scale of 1 : 500,000, by MM. G. Vasseur and L. Carez. This work, which is to be completed during the course of the year 1886, will comprise altogether forty-eight sheets, of which fifteen have already been issued. These include the south coast of England, the greater part of Belgium, Luxemburg, the Rhine to Bonn and Frankfort, Alsace-Lorraine, the eastern and central parts of the Paris Basin, and the neighbourhood of Bordeaux.—Chief results of the systematic researches made in Sweden since the year 1873 on the upper atmospheric currents, by M. H. Hildebrandsson.—Note on the northern limit of the south-west monsoon in the Indian Ocean, by M. Venukoff. It appears from M. Prjevalsky's recent voyage to Northern Thibet that the limit of the south-western monsoon coincides approximately with the 37th parallel of latitude, and stretches west and east from about the head-waters of the Oxus and Tarim Rivers to the meridian of Lang-chew, capital of the province of Kan-su, in West China.—A reply to M. Bourquelot's recent note on interverted sugar, by M. E. Maumené.—Note on the guano of Alcatras, by MM. A. Herbelin and A. Andouard.—Reply to M. Cartailhac's objections on the human remains and pottery recently found in the cave of Nabrigas, by MM. Martel and de Launay. The authors deny the possibility of a post-Quaternary disturbance of the cave, and consequently maintain the conclusions already formulated on the significance of these discoveries.—The death was announced of M. Tulasne, Member of the Botanical Section, who died at Hyères on December 22, 1885.

THE VEGETABLE GARDEN

The Vegetable Garden. Illustrations, Descriptions, and Culture of the Garden Vegetables of Cold and Temperate Climates. By MM. Vilmorin-Andrieux, of Paris. English Edition. Published under the direction of W. Robinson, Editor of the *Garden*. 8vo, pp. 601. (London: Murray, 1886.)

THIS is an English edition of a book which under its original title of "Les Plantes Potagères" has been received with encomiums alike by gardeners and by men of science. Professedly addressed solely to practical gardeners, it is so conscientiously elaborated that it has become, and will remain, a standard book of reference for the naturalist. This is a great triumph for the author, M. Henry Vilmorin. The botanist would at first glance naturally be disposed to consider such a book as at best merely a descriptive trade catalogue of an eminent seed firm, and the biologist might perhaps look askance at the notion of deriving any information of value for purposes of pure science from its pages. But on further examination, it will be found that the merely trade element is ignored, and that the descriptions of the several plants treated of are so carefully drawn up that they will as far as they go meet the requirements of the naturalist.

These descriptions are founded, as we have personal reasons for knowing, not only on the observation of plants growing in the author's seed grounds near Paris, but also on the inspection and comparison of the same or allied forms in the market gardens of Europe generally. The experimental garden of our own Royal Horticultural Society at Chiswick has been utilised in this way, while even the smaller market gardens in the vicinity of Continental towns have not been left unvisited.

Those who have not previously attended to the matter will possibly experience a feeling of surprise at the large number of varieties here enumerated. They are familiar, perhaps, with broccolis and cauliflowers, though they would find it hard to distinguish between them. They might pick out savoys from cabbages, but for the most part they would roughly class such things as "greens," and not pursue the subject further.

While all vegetables are grown for food, subdivisions may be created among them in accordance with special requirements. There are, for instance, the supply of the markets, the exigencies of the exhibition table, the demands of private establishments, and, we might add, the demands resulting from the eager competition of commercial men. The rule of the survival of the fittest has to be applied with special modifications to each of these cases.

Quality is not so much an object of solicitude to the market grower as early or quick growth and abundant produce. The man who can send his produce to market earlier than his fellows has a distinct advantage, and thus it is that foreign competition is so serious an affair for the English grower. Not only from the Channel Islands but from the South of France and Algeria come immense quantities of salads, vegetables, and fruits to our markets. The smaller cost of labour and the high prices obtained balance the expense of the long transit. The home-grower, on the other hand, can continue the supply after the Continental sources have become exhausted, and thus in some cases late varieties are preferred by our growers. But in any case for market purposes on a large scale—for the supply of the general public—the crops must be large, and hence it is that a market gardener will grow what he knows to be "a good cropper" rather than a plant of better quality but which is less productive.

The exhibition tables at our flower and fruit shows, although they foster a good deal of fantastic extravagance, nevertheless effect much good by allowing of the exhibition of numerous varieties, so that the grower may see which is good and which less good, or which is specially suited to his conditions and requirements. They also stimulate the zeal of the growers and powerfully promote good cultivation. This must have been remarked by many at the exhibitions held by the Royal Horticultural Society for the last two years in connection with the "Health" and with the "Inventions" Exhibitions. Such displays render great services to cottagers and others by bringing under their notice new and improved varieties often just as easy to cultivate as those of inferior quality. On the other hand, the "prize system" too often leads to the devotion of an inordinate amount of attention to mere size and external appearance. The bigger and the more symmetrical the exhibit the better the chance of a prize. The huge roots seen at the cattle shows, for instance, are in their way marvels of culture, but their feeding value is considerably less in proportion to others of more moderate size and perhaps less shapely appearance. Water, rather than starch and sugar or nitrogenous compounds, is the predominant element in these overgrown products. When such vegetables as these get prizes the judges are to blame and the societies are doing their work badly.

In private establishments the case is different. While the supply must of course be adequate, the quality of the vegetables is a matter of greater consideration than the mere quantity.

The different requirements we have alluded to entail a corresponding variation in the amount and character of the supply. In addition differences of soil, climate, and other local conditions necessitate other variations. What is suitable for one place is not so for another. When these facts are considered, the wonder that there should be so many varieties will pass off. In most instances these plants have been in cultivation for centuries. They exhibit, some more, some less, the tendency to vary which is the common attribute of all creatures. Having secured a variation suitable for his purpose, whatever it may be, the object of the grower is to fix it and perpetuate it, and only those who have visited our great seed-farms know with what jealous care and with what labour this is effected. When, as is the case with the Brassicas, the facilities for intercrossing are great, the difficulty of preserving a pure stock is intensified.

For scientific purposes, for the purpose of ascertaining the nature and possible range of variation within limited periods, and either under the same or under different conditions, a visit to an experimental garden like that at Chiswick, or to one or other of the great commercial seed-farms, is most instructive.

This aspect of the matter is treated of in the original preface, but we regret to see that it has been omitted from the English version. This is an injury to the book from the point of view of science, and an injustice to the reader, who would value the opinion of so careful an observer as M. Henry Vilmorin. It must suffice here to say that although he recognises the "unstable and perpetually changing characters" of plants, especially when submitted to cultivation, this variation, vast as it is, does not, in his opinion, affect either the number or the position of "legitimate species." M. Vilmorin's natural qualifications and his exceptional opportunities, of course, entitle him to be heard with very great respect, but we suspect most English botanists and cultivators would arrive at different conclusions from the same premises.

Of the value of this book to practical men it is not necessary to speak here: it is because it offers so valuable a storehouse of carefully observed facts of value to the biologist that we have alluded at such length to a volume which might at first be thought to be of interest to gardeners only, but which, we may repeat, is eminently worthy the attention of all those interested in the vast questions connected with variation and inheritance.

There are many points on which we should have liked to have commented, but the exigencies of space forbid. We have only to add that the translation has been well done by Mr. W. Miller, that some practical details have been added to adapt the book for English use, and that a very copious index is provided.

MAXWELL T. MASTERS

PROFESSOR MARSHALL ON THE FROG

The Frog; an Introduction to Anatomy and Histology. By Prof. A. Milnes Marshall, M.D., D.Sc., M.A., F.R.S., Beyer Professor of Zoology in Owens College, Manchester. Second Edition. (Manchester: J. E. Cornish, 1885.)

THE teaching of biological science never received a greater impetus than that which took its origin in the establishment, fourteen years ago, of the laboratory at South Kensington, now associated with the Normal School of Science and Royal School of Mines; and the publication, some three years later, in connection therewith, of Huxley and Martin's "Elementary Biology," marks an epoch no less definite or important. The large number of teaching laboratories which have since been founded, wherever the English tongue is spoken and even on the Continent, have almost without exception been modelled directly or indirectly upon the Kensington plan. Practical directions for working have been issued in connection with most of them, compiled along the lines of Huxley and Martin, but specially adapted to the requirements of the individual schools. Of these, most are still alone used in the dissecting rooms for which they were written; some few have, however, been published separately, the volume before us being one of their number.

The author's name is a guarantee of the thoroughness of the work, and he has done well in taking such a prototype for a guide. We read in the preface that the book is a first instalment, to be followed by a second dealing with "types of the principal zoological groups;" as the ultimate success of the project will depend upon the selection of these types, and especially upon the evenness of balance maintained in dealing with them, we reserve full criticism until the completed work is before us.

The present edition is mainly noteworthy for the introduction of illustrations—fifteen in number. The original ones are for the most part somewhat rough, though accurate in detail, and they have the merit of representing the structures as they will meet the eye of the student. Fig. 10, however, would bear recutting, for if the bones are "represented black" why not the columella-auris; and continuity should certainly be shown between the brain and very sketchy labyrinth. The maxillo-palatine commissure—described (p. 84) in its proper place—should also find a representative in Fig. 13, and in connection with the renal-portal vein of Fig. 4 afferent renal branches might be advantageously introduced. The relation of the mesentery to the kidneys in Fig. 2 also needs looking into.

The text bears the mark of a writer in full sympathy with the difficulties which beset a beginner; more importance might, however, well be given to a consideration of those matters of symmetry, locality, and general utility, which must be mastered before studying anatomy proper. The customary restrictions put upon at least the terms *anterior*, *posterior*, *lateral*, should be clearly set down in addition to those given on p. 13 and elsewhere, and the positions of the organs should be described accordingly. If this were so, the description of the liver given on p. 17 would, for example, be more accurately rendered than it is.

It would facilitate the demonstration of the bile ducts in so small an animal, if the student were directed to simply squeeze the gall-bladder after having opened up the intestine, instead of risking the insertion of a destructive bristle as advised on p. 20.

A special feature has been made of the histological section of the work, but, granting its thoroughness, we would fain see some of the frog's tissues retained for those supplemented from other animals, especially in the case of bone, where so highly instructive an example as that of the long bone is to hand. In describing the nerve fibre the nodes of Schmidt have been overlooked, but here our author is not alone; considering the years that have elapsed since their discovery, it is strange that they should only recently have found mention in our English text-books. Reflecting on the doubtful nature of the so-called non-medullated nerve-fibres, it is a pity that the ultimate ramifications of a medullated fibre in so out-of-the-way a place as the cornea should be made (p. 89) to do duty for them.

The book is neatly and carefully got up, but a future edition should not be published without an index. The description of the mesentery in relation (p. 18) to the alimentary canal, and those of the attachments of the corpus adiposum and testes (p. 17) might well be much modified; and the like is true of the statement that the skeleton gives (p. 45) "precision to the movements" of the body. The heading (p. 48), "peculiar vertebræ," is bad, and olfactory *sacs* reads on p. 49 "olfactory nerves," in error. A somewhat remarkable typographical error is the "mpanic cavity" of p. 98.

In conclusion, we would take exception to the references (pp. 28 and 74) to the suppressed aortic arches of the embryo and to the mode of development of the nervous axis, unless their introduction bears upon the lecture scheme adopted at the Victoria University. If so, well and good, but if not, we are of opinion that such supplemental statements should be inserted, in a book of this kind, as footnotes or their equivalents. It is sufficient that the beginner should realise that three pairs of aortic arches exist in the adult, alone under consideration.

OUR BOOK SHELF

Methods of Research in Microscopical Anatomy and Embryology. By C. O. Whitman, M.A., Ph.D. (Boston: S. E. Cassino and Co.; London: Trübner and Co. 1885.)

WITHIN the last few years a number of new methods have been suggested for use in microscopical, and more particularly embryological, research, and a glance at almost any one of the recent memoirs on these subjects will serve to show how much is due to the employment of new methods. It is, however, extremely important not to lose sight of the fact that complicated methods are exceedingly likely to produce false or misleading appearances. To carry on successfully any microscopical research it will probably be necessary to invent new methods or at any rate modify old ones to suit the exigencies of the case. To do this an acquaintance with the methods which have been used by previous observers is necessary, and in addition a clear idea of such general principles as it is possible to formulate with regard to the action of various classes of reagents upon various tissues.

A great number of the new methods have been described, and this often in a few words only, in special memoirs, so that they are often overlooked.

"Hitherto," says the author of the work before us, "most of our standard books of reference on methods have been rather complex in character, dealing with the microscope and technical methods as subordinate and introductory to the main subject of histology."

With regard to certain special methods there appears unfortunately to be a reluctance on the part of their inventors to reveal what they thus make a sort of trade secret, "withholding it on the ground that others are not entitled to the advantages of your experience." Dr. Whitman in his present work has sifted the numerous methods which have been suggested, and has given histologists the benefit of his great practical experience in rejecting some while recommending others; he has also endeavoured to formulate as many general principles as possible, though of course there is more to be done in this respect, our knowledge being at present insufficient to generalise to any great extent.

We notice with regret a slight tendency in the work before us as well as certain histological schools to neglect almost entirely the older and simpler methods of cutting sections. Serial section-cutting is now such an important item in all morphological work that it is apt to be used to the exclusion of older methods, which give in many cases undoubtedly better histological results.

Dr. Whitman has also collected a large number of most important observations with regard to the best method, time, and place of obtaining material; these are of course very incomplete, but it is to be hoped that he will see his way towards continuing them, and that others will follow his excellent example.

Alternating Currents of Electricity. By Thomas H. Blakesley, M.A. "*Electrician* Series." (London: Published at the Office of the *Electrician*, 1885.)

THIS is a very unsatisfactory little book; indeed it is difficult to find anything favourable to say of it, except that it is concerned with a subject which is of considerable importance, and which might be treated in an interesting and instructive manner. It is a reprint of papers, originally published in the *Electrician*, on Alternating Currents of Electricity, and professes to deal with various problems connected with them by geometrical methods. But the methods are long and intricate, and the work is not well done;—carelessly written and printed in the beginning, the style remains unchanged. The errors in form are numerous, the figures are not good, and geometry and algebra are mixed up in formulas in the most puzzling and irritating way. We find commas between the factors of products (all through pp. 11, 12, 13), and diagrams in which the letters are illegible in several places. In one investigation covering three or four pages, we have the letter *C* used for capacity of a condenser, for electric current, for the sum of a series of cosines, and for designating points in the diagrams. In fact the whole book is full of confusion, and is a model of what mathematical writing ought not to be; while we cannot imagine that it will prove useful or even intelligible to the telegraph engineers for whose benefit we may suppose it was put together. J. T. B.

Third Annual Report of the New York Agricultural Experiment Station, for the Year 1884. (Albany, N.Y.: Weed, Parsons, and Co.)

THIS Experiment Station was established by an Act of Legislature passed in 1880, and amended in 1881. The management is intrusted to a Board of Trustees, who appoint a director, horticulturist, botanist, chemist, stenographer, farmer, and assistants. Such an organisation must be considered as a step in advance beyond anything yet done in this country, being a direct action on the part of the Government to promote the exact knowledge of agriculture. This is the main point we desire to bring before the readers of NATURE. Among the many voices raised on behalf of technical instruction of artisans and others engaged in industrial pursuits, or of musicians and artists, few are to be heard in favour of the promotion of exact agricultural knowledge. The Americans are wiser, and are establishing what they call "experiment stations" in various parts of their wide territory. A few of the objects of investigation at present occupying the attention of the staff of the New York Station may be enumerated as follows:—(1) Fertiliser analysis; (2) sample orchards containing single trees of each known variety; (3) soil temperatures at various depths; (4) digestibility of various foods; (5) germination of commercial seed; (6) a study of maize; (7) root-distribution by root-washings; (8) milk; (9) diseases of plants. These sections furnish material for 418 pages, abounding in tables of results of great practical value. The pains taken in thoroughly working out the conditions of milk-production in the case of two cows, "Meg" and "Gem," are evidence of great activity and zeal. The weight of the cows was taken daily from September 17 to November 12. The weight of food consumed, the accurate analysis of the food, the *daily* weight of solid and liquid excrements, the *daily* yield of milk, the *daily* analysis of the milk,—all this carefully and punctually recorded, and fixed in tables, is a work of great importance, not only as bearing directly upon dairying, but having likewise a physiological value. Such constant daily observations are not only essential, if the experiment is to be of any practical value, but must be beyond the efforts of practical farmers, who really ought not to undertake such investigations. But the value to the community at large when such experiments are conducted quietly and regularly by persons specially set apart and paid to carry them out cannot be overrated. They must not be attempted by ordinary dairymen in ordinary stalls, and with ordinary business appliances, but can only be carried out by trained hands, in specially constructed stalls and with special arrangements, all of which must be carried out at a *loss*, which loss is the reason for an endowment. It is hard to say whether the perusal of such a Report as now lies before us impresses most with admiration for American activity or regret for English supineness. JOHN WRIGHTSON

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Major Greely on Ice, &c.

IN the long and interesting address of Major Greely at the special meeting of the Royal Geographical Society, held ten days ago, with the object of hearing an account of some of his proceedings during his painfully memorable Arctic expedition, the traveller dwelt so largely upon the conditions of the ice on the open Polar sea, &c., that one was led to believe that he was talking *at* opinions—spoken or written—by some one adverse to his own; possibly those given by myself in the communication published in NATURE of December 10 last may have been meant. Should this be so, anything that Major Greely has said does not in the slightest degree affect the statements made by me in the above-mentioned letter.

Major Greely tells us that Hayes, as well as *Kane* (it should be *Morton*), saw "an open Polar basin." Payer, in as high or a higher latitude at Franz Josef Land, saw, at a much earlier date in spring than Hayes and Morton did, a larger pool of open water, with "myriads" of water-fowl, but did not think of calling it an "open Polar basin," or part of one.

This idea of a great open Polar sea is almost, if not wholly, confined to our American cousins, where it seems to have taken firm root for at least thirty years past, and has, I should imagine, a spiritualistic origin, for Dr. Kane was a believer in spiritualism.

With the fear of appearing tedious, I shall quote briefly the perfect meaning, if not the exact words, of part of a letter which a distinguished spiritualist, Major ——, sent to me prior to one of my Arctic expeditions. In this letter I was told that Franklin was still alive (clear proof had been obtained that he had been dead some years before the date of a *part* of this letter), and was residing at 132 (?), St Peter Street, in a seaport town called Joppa, having a population of more than 100,000 persons, on one of the lands near the Pole!

There was a large population, the Government Republican, and a fine, healthy, and salubrious climate. "These *people were descendants of one of the lost tribes of Israel*"!

The postscript was curious, and written at a later date than the letter itself, immediately after the death of Dr. Kane, as follows:—"Have just had communication with the spirit of Dr. Kane, whose first visit after death was paid to Franklin in Joppa, where he was still alive and well, but praying to get home."

Major Greely seems to confound two forms of ice having very different origins—namely, the floeberg, of which I have already said enough elsewhere, and the freshwater-ice, which, he says, is derived from the ice-caps of far northern lands, a mass of which he saw, having very considerable extent and "a thickness of one-sixth of a mile! with a deep valley containing a number of boulders."

This great mass of ice, 880 feet thick, with valley and rounded stones, may have been readily formed on the shores of one of the high headlands—one of which is named as having an altitude of nearly 3000 feet—along the northern portions of which Lieut. Lockwood skirted during his sledge journey on the coast of Greenland.

True, I was never in these high latitudes, but a person may sometimes be permitted to reason from analogy, as I shall attempt to do.

In 1848 I saw on the northern shore of America, in lat. 68° 40′, not far from the Coppermine River, a snowdrift against a cliff about 100 feet high, and in 1849 I and my party were detained at the same place for a good many days, during which we had ample time and opportunity to examine this snowdrift, nearly all of which was converted into ice that seemed permanent, except when parts broke off and floated away.

The slope of this snowdrift tapered towards the sea with so gentle a descent that our boat was easily hauled upon it to protect it from the ice-pack, and we with great facility carried our baggage up the ascent, and pitched our tent on the top of the cliff. A part of this snow-drift ice had broken off and drifted away, showing a very distinct stratified section, similar to that described by Dr. Moss and Major Greely.

The height of this section above sea-level was only, as far as I can remember, about 10 or 12 feet, for the water is shallow on this coast,[1] but, if Major Greely's measurements are correct, the

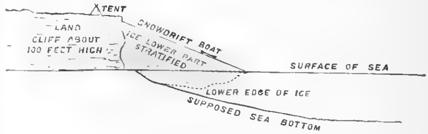

FIG. 1.—Actually seen by J. Rae in 1849, at a headland north of Coppermine River, lat. 68° 40′.

water close to the Greenland shore must be pretty deep—at least 100 fathoms—so as to float ice one-sixth of a mile thick.

My contention is that, if in latitude 69° a drift-bank of snow and ice is kept up from year to year against a cliff 100 feet high, the same thing may take place in latitude 82° to a far larger extent, where the shore is 2000 feet high, steep or precipitous, and the sea deep, so that masses of ice 800 or 900 feet thick may break off and float away.

That such great sloping snowdrifts do occur on the northern Greenland coast was proved by the difficulty met with by one of the officers of the English Expedition in travelling along them in 1876 with sledges, being forced to do so in many places by the rough ice outside, which stopped the way along the level floe.

As regards boulders, they are to be found of various sizes, more or less numerous, almost everywhere on Arctic lands high above the present sea-level, and they might have been transported to the "valley" spoken of by Greely in other ways than that supposed by him. They may have been moved downwards very slowly, by the alternate freezings and thaws of the snow and ice round them, by storms and snowdrifts, then down the slope of the valley to its lowest level, or they may have been carried by one of those streams of water similar to that mentioned as running down over the snow-caps of Grant Land. In fact, all that is wanted for this purpose would be two high,

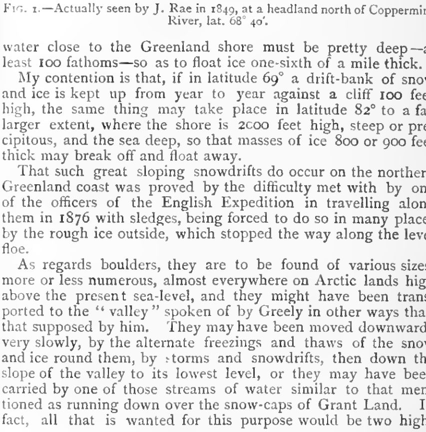

FIG. 2.—Supposed headland on the northern part of Greenland, about 1500 feet high. Greely says these headlands (or one of them) are nearly 3000 feet, having a northern or north-eastern aspect.

steep bluffs, with a deep narrow ravine between. The bluffs would give the thick masses of snow and ice-drift, and the ravine might form the bed of a stream carrying stones into the valley.

Neither Dr. Moss nor Major Greely, as far as I have noticed, have accounted for the very distinct stratification seen in the form of ice described. In all parts of Arctic America where I have been, a fall of snow is usually either accompanied or followed by a gale of wind more or less strong, chiefly from one

[1] In the very rough sketch sent, the water is made to appear much too deep; in fact, there is no pretence at correct proportion of heights and distances.—J. R.

direction, with thick snowdrift, which cuts away earth and sand in minute particles from the windward side of any hill or rising ground in its course, and these particles are carried along until they find a resting-place under the lee of some steep bank or cliff.

These foreign substances, when mixed with a great depth of snow, are not readily seen, but when the spring evaporation and thaws remove a great part of the snow, a stratum—more or less thin—of coloured matter, is visible on the surface, and this marks clearly the stratum or formation of one season. No doubt, sometimes, if there happen to be a minimum of snowdrift during the winter, followed by an unusually warm summer, all the winter deposit of snow may be removed, and the earthy deposit (naturally smaller than usual) will be added to that of the previous year.

It may be asked why I did not speak of these matters in Major Greely's presence at the meeting of the Geographical Society? This is easily explained: Major Greely's address was so long that little time was left for discussion, and this time was most properly given to the officers (four of whom were present) of the English Government Expedition of 1875–76, who, to my surprise and amusement, let the astute citizen of the United States have things pretty much his own way. In fact, one of these officers made matters rather worse than better by what he said. JOHN RAE

4, Addison Gardens, Kensington, W., January 1

Hydrophobia—A Further Precaution

IT may be taken as an accepted fact that mongrels are more liable to rabies than well-bred dogs, both from the ill-treatment they commonly receive, and from the unnatural mingling of species that has led to their production. Statistics show that over 90 per cent. of mad dogs are retrievers, or animals so-called. In addition to these two points, it can be safely maintained that no kind of dog gives birth to so many mongrels as the retriever. Pointers, setters, terriers, and hounds will not readily breed from dogs of another class, but the reverse is true of the retriever, and the result is the production of a horrible progeny that ought to be immediately destroyed. Owners of a kennel of sporting dogs are constantly subjected to the annoyance of one of their true-bred retrievers having a litter of pups that only resemble retrievers in their coats. I would therefore suggest that the Retriever Stud Book should be kept by a Government official, and that all owners of retrievers should be obliged to send notice to him when a litter arrived; and that the police should be empowered to destroy any retriever whose owner was not provided with a certificate of registration. A few inspectors of litters could travel the country, and at a cost of a few hundreds a year prevent the development of countless mongrels—valueless for sporting purposes, hideous to look at, and sure promoters of canine madness. H. M. TOMLIN

Rotation of Mars

PROF. BAKHUYZEN is right in regard to the number of days counted in error by Kaiser in comparing Hooke and Huyghens with recent observations. I wrote away from books, and with no means of determining whether Kaiser had made Hooke's observation a day too early or a day too late in comparing it with Huyghens's—which was what in reality he did. I saw that three days' correction would about bring matters right, and knew that in 1873 I *had* brought matters right; so concluded that was the way. But, being in London for a few days, I have looked up my paper of 1873, and find that the correction was obtained by omitting two days from Kaiser's count between Huyghens and himself, and adding one day to his count between Hooke and Huyghens.

I have not seen Prof. Bakhuyzen's paper, and the pressure of more serious business (life-duties) prevents me from giving time to such examination of it as I gave to Kaiser's in 1873. The results, however, were and are before me. It was natural I should infer that he had taken Kaiser's results as they stood. For, the comparison of either Hooke or Huyghens, using Kaiser's own dates and estimates (following him, in fact, in everything except his clerical errors in regard to the New Style date for Hooke's observations, and to the number of days in 1700 and 1800), gives no such results as Prof. Bakhuyzen has presented. Kaiser made the interval between November 1, 1862, 6h. 10·1m., and August 13, 1672, 12h. 10·3m. (at which epochs he found Mars to have been in the same position in regard to sidereal rotation), to be 69476d. 17h. 59·8m., and in this period, he said, Mars made 67,719 rotations: the resulting estimate of the rotation-period is 24h. 37m. 22·64s. In reality the interval was 69474d. 17h. 59·8m., and in this interval Mars made 67,717 rotations: the resulting estimate of the rotation-period is 24h. 37m. 22·71s. Again, using the observations of Hooke and Huyghens combined to give a mean, and the mean of the best observations between 1830 and 1870, we deduce the period 24h. 37m. 22·71s., which was, I find, the value I indicated as the most probable in 1873. Using observations up to those in 1884, I find for the period 24h. 37m. 22·703s. I find no noteworthy correction on using Maraldi's or W. Herschel's observations, with which, indeed, my inquiry began. I am satisfied the seconds are nearer 22·7 than 22·64.

RICHARD A. PROCTOR

A Meteor

AT 4.47 p.m. yesterday, whilst returning home with two friends, I saw a large meteor pass slowly downwards in an east-north-easterly direction. Unfortunately it was twilight and very cloudy at the time of the observation, and the "fireball," as one of my friends called it, was consequently shorn of much of its brilliancy. It was, however, distinctly visible behind a thin veil of cloud, and when seen for a couple of seconds in the open it seemed to have an apparent diameter about four times that of the planet Venus, which, with the crescent moon, were the only other conspicuous objects in the heavens at that time.

Brighton, January 10 W. AINSLIE HOLLIS

Meteorological Phenomena

I HAVE just received the inclosed notice of a meteorological phenomenon which you may consider of sufficient interest for publication in NATURE. HENRY TOYNBEE

Meteorological Office, 116, Victoria Street, London, S.W., January 6

LEAVING the port of Kingston, Jamaica, at dusk on November 23, 1885, the night was fine and starlit overhead, but about 8 p.m. a heavy bank of cloud obscured the island, and all around the upper edges of this cloud-bank brilliant flashes of light were incessantly bursting forth, sometimes tinged with prismatic hues, while intermittently would shoot vertically upwards continuous darts of light displaying prismatic colours in which the complementary tints, crimson and green, orange and blue, predominated. Sometimes these darts of light were projected but a short distance above the cloud-bank, but at others they ascended to a considerable altitude, resembling rockets more than lightning. This state of matters continued until about 9.30 p.m., when all display of light ceased. As I have never seen such a phenomenon in any other part of the world, I have deemed it an unusual occurrence, and worthy of record.

R.M.S. *Moselle*, Southampton T. MACKENZIE

I SHALL be obliged if you will allow me to record in your columns the following account of some remarkable phenomena witnessed during a voyage from Sunderland to London, and I trust that if you are good enough to insert this letter, it may be the means of eliciting some explanation from yourself or your readers as to the causes producing such strange effects. Capt. Herring, of the s.s. *Fenton*, reports to me as follows:—

"We left Sunderland at 3 p.m. on the 7th inst. bound for London, wind west-south-west, with snow squalls and strong sea; towards midnight wind increased, and the squalls cyclonic. When between Flamborough Head and Scarborough, the vessel became enveloped with phosphorescence, the mast-heads exhibiting the curious phenomenon known by sailors as 'Composants' (*corpus sancti*), which in this instance were shaped like a top, about two feet at the widest part, resembling a bunch of mistletoe illuminated. The standing rigging and all protruding objects were in like manner illuminated, and the most extraordinary effect was produced when the mate, who was on the bridge with me at the time, raised his head above the canvas weather-sheeting; the whole of his hair, exposed, and beard were instantly illuminated, and in like manner his hands when elevated became phosphorescent on the outline of his mittens. When under cover of the sheeting there was no appearance of phosphorescence; it would therefore appear that the effect of the wind produced the phenomenon. The weather towards morning moderated, and brilliant flashes of lightning were seen to the eastward." CHARLES WEST

Lloyd's, London, E.C., January 11

The Admiralty Manual on Terrestrial Magnetism

IN a recent number of NATURE you mention that the new edition of the Admiralty Manual on Terrestrial Magnetism is being edited by me. It gives me great pleasure to be able to inform those interested in this work that I have obtained the advice and assistance of Capt. Creak and Mr. Whipple as to the changes required in the description of the ship- and land-observations respectively. From the guidance of such able specialists I feel that the work will have a value that it could never have had from my unaided exertions.

GEO. FRAS. FITZGERALD

Trinity College, Dublin, January 6

Anchor Frosts

ON the night of Friday, January 8, there was an anchor frost in the Cherwell such as has not been known for twenty years, according to people who have lived at a mill on the river (Clifton Mill, near Aynho Station) for that period. In a mild form the phenomenon is fairly frequent there. The most marked effects are seen in comparatively still water.

Thus, in the mill-pond, where the current is stopped by the mill during the night, the whole stream becomes semi-viscous. Roots beneath the water, the brickwork at the sides of the mill-pond, &c., are seen to be coated with ice beneath the water as far down as can be seen, and between this ice and the surface ice-crystals form, not in a sheet or block, but interlaced loosely, like snow crystals in a drift. The mass thus formed blocks the channel, and it is said that water coming upon it from above will rise in level and flow over it, as over a solid obstruction. This I have not seen myself.

When the mill is started, at first the water will hardly flow past the wheel; but at length the crystals are forced to the surface, where they remain in floating masses, under which the water flows as usual.

The surface is not covered with a sheet of ice in these frosts.

In a broad, shallow ditch at right angles to the river, where the water is comparatively still, similar effects could be seen: the pebbles at the bottom coated with ice and the water filled with loose crystals. One consequence of the bottom ice forming on this occasion was that the floodgates were frozen down on the Friday evening, so that they could not be drawn up as usual, and the river overflowed during the night. In the morning, when they were at last raised, the water would hardly flow through, as already mentioned in the case of the water-wheel. T. HANDS

Clifton Mill, near Aynho Station

Curious Phenomenon in Cephalonia

I BEG leave to forward to you an extract from a letter which I have recently received from a friend and former pupil who is at present an officer on board one of Her Majesty's ships in the Mediterranean. I have never seen any reference to the phenomenon which he describes. If you can insert the extract, perhaps it may evoke further information with regard to it. I would not forward the statement unless I had every confidence in the writer, so that I do not think he would be likely to be easily deceived or mistaken in his observations. He is a gentleman who took an excellent position in the Cambridge Mathematical Tripos. E. LEDGER

Barham, January 7

"By the way, at Cephalonia there is a very remarkable phenomenon. The sea runs into the land in a strong stream, turning a water-wheel on the way, and disappears in the earth about a hundred yards from the entrance. Can you explain this? I believe no one has yet done so. No part of the island is below the level of the sea, nor is there any salt lake or spring in the island. I imagine this water must be converted into steam, which comes out either at Naples or Stromboli."

SIR F. J. O. EVANS

CAPTAIN SIR FREDERICK J. O. EVANS, R.N., K.C.B, F.R.S., late Hydrographer of the Admiralty, died at his residence, 21, Dawson Place, on December 20, 1885, in his seventy-first year.

This eminently scientific officer entered the Royal Navy in the year 1828, and served in H.M. ships *Rose* and *Whinchester*, on the North American station, until 1833, when he was transferred to H.M. surveying-vessel *Thunder*, Commander Richard Owen, and was employed until 1836 in surveying operations in various parts of the West Indies.

It was in this ship, and under the guidance of her able Captain, that he imbibed those scientific tastes which formed his character later in life, and laid the foundation of a career of usefulness, uninterrupted to its close, and which has perhaps rarely found a parallel in the naval profession.

Mr. Evans subsequently served in the *Caledonia*, the flag-ship in the Mediterranean, the *Asia*, the *Rapid*, the *Rolla*, the *Dido*, and *Wolverene*, of which two latter ships he was acting master. He was confirmed in that rank in 1841, and was then appointed to H.M.S. *Fly*, Capt. F. P. Blackwood, fitting for special exploring and surveying service in Australia and New Guinea, where he was continuously employed until 1846. He took a very leading part in the examination of the Coral Sea, the Barrier Reefs of Australia, Torres Strait, and the neighbouring shores of New Guinea, regions then comparatively unknown. After a short period of surveying service on the home coasts, Evans was appointed to the *Acheron*, under the late Admiral Stokes, and was engaged until 1851 in exploring and surveying the coasts of the then young colony of New Zealand; in both these important enterprises he took a very conspicuous part, and gained for himself the reputation of a skilful and scientific surveying officer, second to none in the profession.

During the Russian war Evans was employed in the Baltic on special reconnoitring service, and was attached to various ships of the fleet, taking an active part in the operations against Bomarsund and among the Aland Isles, for which he was mentioned in gazetted despatches.

It may be truly said that for many years of his life Evans was a zealous contributor to magnetic science. He had already begun to make observations of the three magnetic elements whilst employed on hydrographic work in H.M. ships *Fly* and *Acheron* in the Australian Colonies and New Zealand, between the years 1842–1851; but it was not until 1855, when he became Superintendent of the Compass Department of the Royal Navy that he was able to devote himself entirely to the magnetism of iron ships, a subject which was then growing yearly in importance, from the increasing amount of iron used in fitting as well as construction even before iron plating had brought about an actual crisis.

Sagaciously foreseeing the important part the science of magnetism was destined to play in the Navy, then being revolutionised by the change from wood to iron, he devoted his whole energies to the study of the subject until he had made himself completely master of it.

In 1865 Capt. Evans was appointed Chief Assistant to the Hydrographer, retaining his position as head of the magnetic department; this post he continued to hold until the early part of 1874, when a vacancy occurring in the Hydrographership of the Admiralty he was selected to fill it, and continued to do so with equal ability and conscientiousness until within a little more than a year of his death.

From the time of his first appointment in 1855 as Chief of the Admiralty Compass Department until his death Capt. Evans (in happy co-operation during a great part of the time with that great mathematical genius Archibald Smith) devoted himself heart and soul to the solution of what was really a question of life and death to the British Navy, and indeed to seafaring people all over the world. The question was whether it was possible so to deal with the disturbing element of iron, then entering largely into the construction of ships of all kinds, as to prevent the time-honoured compass from becoming a useless toy, or even a misleading guide. Now that the difficulty has been grappled with and conquered, we have half learned to forget the magnitude of the peril. But for the scientific and practical progress due to the labours of Capt. Evans and Archibald Smith we might almost with advantage have thrown all our compasses overboard. The attraction due partly to the inherent and partly to the induced magnetism of iron ships, and especially of plated ships, was so violent as to induce in some vessels, in certain positions, errors of two, three, or four points of compass indication. Something had been done to explain the causes of the mischief and to suggest palliatives. Famous old Flinders, at the beginning of the century, had spelt out the mystery so far as it was disclosed by the wooden ships of his time, but he had to deal with comparatively minute errors due to induction alone, and was never brought face to face with the stupendous difficulty which iron shipbuilding and iron ship-plating, afterwards created. The late Astronomer-Royal had done good and sound work in the earlier days of iron, but much more was needed to overcome the serious trouble which the newer types of mercantile and still more of naval vessels threatened to bring upon us.

It was at this critical epoch that Capt. Evans and Archibald Smith began to work together. Years of experimental labour and mathematical research went to the production of the "Admiralty Manual on Deviations of the Compass"—a book perhaps as perfect in its kind as a book could be. It is hard to do justice to the elegance of the mathematical handling, and, above all, to the happiness of the graphic methods which are found in the Manual, without seeming to indulge in extravagant laudation. An enthusiast in such matters once pronounced it a piece of lovely work, and one need not be an enthusiast to appreciate all that the epithet was meant to carry. Capt. Evans would have been the last to deny that the larger part of the purely theoretical investigation was due to his brilliant fellow-worker. Indeed his modesty often prompted him to claim less than his fair share of the credit due to both. The subject was one which called for the combination of practical sagacity and experience with refined scientific method—and if Archibald Smith was the stronger on the one side, Capt. Evans was his master on the other; nor was either of them without large powers, even in the special department of their joint labour in which he owned the supremacy of his friend. It was an undertaking which called for the united effort of just two such men as were fortunately brought together to do it, and the result has been a triumph to England and a blessing to the world which will preserve the memories of its authors as long as the ocean remains the highway of Englishmen and of the world.

The death of his old colleague did not abate the zeal of Capt. Evans, and few years passed since that time without some notable addition from the hands of the Hydrographer to our existing stock of experimental knowledge and scientific theory upon the subject which he had made his own. Much of his work will be found in the *Philosophical Transactions* of the Royal Society, and in 1870 he published an elementary manual supplementary to the Manual; both these works have been freely translated on the Continent, and are the acknowledged text-books in our own and foreign Navies to the present time.

The various steps of Evans's work may thus be stated:—

In 1858 a Chart of Curves of Equal Magnetic Declination, compiled by him for that epoch, was published by the Admiralty. This chart appeared most opportunely, for, with compass errors growing in amount and complexity, the mariner was by means of it enabled to ascertain in any part of the navigable world how far his compass deviated from the magnetic north.

In 1859 he read a paper on the magnetism of iron ships at the Royal United Service Institution. This was valuable *résumé* of all that had been hitherto done in order to obtain a knowledge of the magnetism of iron ships and the treatment of their compasses. He also communicated some results of Archibald Smith's method of analysis as applied to the errors of the compass found in H.M. ships.

Evans's next paper consisted of a Report to the Hydrographer of the Admiralty on Compass Deviations in the Royal Navy. It treated of the magnetic character of the various iron ships in the Navy, and also of the *Great Eastern* steamship. The results of this paper were (1) to show the best direction for building an iron ship; (2) the best position for placing her compass; (3) the various sources of error affecting a compass under favourable conditions. This report was communicated to the Royal Society, and published in their *Transactions* in 1860.

In 1861 he read a paper of similar import before the Institute of Naval Architects.

Reference has already been made to his work on the *Great Eastern*, and an important result of it was the experimental investigation which he was led to make as to the cause of the abnormal errors of the compasses in that vessel, proceeding from the application of Airy's system of magnet and soft-iron correctors when long single-compass needles are used.

With Evans principally as an experimentalist and Archibald Smith as the mathematician, a valuable paper on the proper length and arrangement of the needles on a compass card, together with exact information as to the proper arrangement of magnet and soft-iron correctors with respect to it, was presented to the Royal Society in 1861, being the result of the joint work of those ardent investigators into the compass question in iron ships.

Commencing with this latter paper, we find Evans and Smith as we have said above, generally working together, and under their joint editorship there appeared in 1862 the first edition of the "Admiralty Manual for Deviations of the Compass." The introduction, however, of armour-plated ships soon rendered a new edition necessary, and in 1863 it was published. This work was again revised in 1869, and became the text-book of the world on the important question of the deviations of the compass in iron ships of whatever form, being translated into all the principal European languages.

In 1865 Evans and Smith produced another important paper on the "Magnetic Character of the Armour-plated Ships of the Royal Navy," which was published in the *Phil. Trans. Roy. Soc.* The novelty of the form of ships thus discussed as regards their magnetic character caused the results to be of more than usual interest, and showed with what degree of confidence compasses might be placed in positions where both helmsman and officer might have armour protection.

The practicability of determining the magnetic coefficients without swinging, and also of ascertaining the heating error without inclining the ship, was also demonstrated, and has since been largely adopted in the Royal Navy.

In 1866 proposals were made by Mr. Evan Hopkins, C.E., to depolarise the iron hulls of ships by means of electro-magnets, and he was allowed by the Admiralty to experiment on the *Northumberland*, an armour-plated ship lying in the Victoria Docks. With the increasing difficulty of finding suitable positions for the compass, the prospect of being able to depolarise an iron ship was very attractive. In an able paper, however, read before the Royal Society in 1868, Evans showed that, so far from the hull of the *Northumberland* being depolarised, a portion of it was only temporarily, and therefore dangerously, polarised, and afterwards returned to its normal condition, thus preventing similar experiments being tried with other ships of the Navy.

It was only natural that a joint editor of the "Admiralty Manual for Deviations of the Compass," who knew the difficulties of that work for his fellow-seamen, should wish to present the subject, on which he had worked so long, in an elementary form more suitable to their every-day requirements. Evans therefore, in 1870, published his "Elementary Manual for Deviations of the Compass," a work which has been very well received by the nautical world, and has been translated into various European languages.

With the exception of some papers read at certain meetings of the British Association, and two lectures read at the Royal United Service Institution in 1865 and 1872, Evans subsequently relaxed his personal investigations into the magnetism of iron ships, and turned more to terrestrial magnetism.

Thus, in 1872, he contributed a paper to the Royal Society, on the magnetic declination in the British Islands, and compiled the magnetical instructions for the voyage of H.M.S. *Challenger*, being again assisted in this, and for the last time, by his old fellow-labourer, Archibald Smith.

Lastly, in 1878, Evans read an able and instructive lecture, on the magnetism of the earth, before the Geographical Society, showing the distribution and direction of the earth's magnetic force and the changes in its elements as then known.

Capt. Evans was elected a Fellow of the Royal Society in 1862. He sat for many years on its Council, and was more than once a Vice-President. He was also a Fellow of the Royal Astronomical and Geographical Societies; he served for many years as member of the Meteorological Committee of the Royal Society, and on the change in the constitution of that body became a member of its Council.

In recognition of his public services the Companionship of the Bath was conferred upon him in 1873, and in 1881 he was advanced to the Commandership of the same order.

Sir Frederick Evans's last public service after his retirement from the Admiralty in 1884 was as the British Delegate at the Congress of Washington for the establishment of a prime meridian and questions kindred to it.

JOHN MORRIS

PROFESSOR JOHN MORRIS died on Thursday, January 7, having been laid aside by illness for several months. Born at Homerton in 1810, he spent almost the whole of his life in or near London. For many years a pharmaceutical chemist at Kensington, he passed all his spare time in exploring the neighbourhood of the metropolis and in collecting from field and book the great store of geological knowledge which was one of his especial characteristics. But science claimed more and more of his time, and at last he abandoned business entirely. In 1855 he was appointed Professor of Geology at University College, London, which post he held till 1877, when he was succeeded by Prof. Bonney. In 1878 the honorary degree of M.A. was conferred upon him by the University of Cambridge.

Morris was elected a Fellow of the Geological Society in 1845, and, whilst in health, was a constant attendant at its meetings. He received the first Lyell Medal in 1876, and has four times received the Wollaston Donation Fund. In the Geologists' Association he has been an earnest worker, having been twice its President, and always one of the foremost leaders at its excursions.

The earliest publication by Prof. Morris was "Observations on the Strata near Woolwich," in the *Magazine of Natural History* for 1835. Most of his own descriptive papers refer to the south-east of England and in the Oolitic districts, but in association with others he has done important work elsewhere. His paper with Murchison, "On the Palæozoic and their Associated Rocks of the Thüringerwald and the Harz," read before the Geological Society in 1855, is still one of the best accounts of those districts in the English language. He was joint-author with Dr. Lycett of an important monograph for the Palæontographical Society on the Oolitic Mollusca.

Considering the enormous amount of information stored in Morris's mind, one is surprised that comparatively so little original work came from his pen, and especially that so few species of fossils except those of the Great Oolite bear his name as their author. For this, however, we may perhaps be thankful; he may have been equally well employed in reducing the number of those already in use. This he did to good purpose in his "Catalogue of British Fossils," the first edition of which was published in 1843, the second in 1854. From that date onwards he was engaged in collecting materials for a third edition, which unfortunately he did not complete. Every working geologist and palæontologist has made constant use of this book, and those who have used it most best know the vast amount of labour which its preparation entailed. It is not a mere list, compiled from various authors; but nearly every species has been critically examined and the synonymy carefully traced.

Fond of conversation, a ready and pleasing public speaker, Morris was always glad to impart his knowledge to others. This knowledge was varied and exact; minerals, rocks, and fossils were equally familiar to him, and he was well read in the wider questions of physical geology.

He was held in high regard by all who knew him; and those who gathered around his grave at Kensal Green came to pay the tribute of personal friendship not less than that of admiration for scientific worth.

DISTRIBUTION OF DRIVING-POWER IN LABORATORIES

A NOVEL arrangement has been adopted at the Physiological Laboratory at Cambridge, and at the Owens College, Manchester, for driving instruments in various rooms by means of a central motor. At the Brown Institution shafting has been used for the same purpose. This method is commonly used for driving machines which require a good deal of power, but it is not suitable for laboratories where the power is often required in many rooms, on different floors and some distance apart, thus causing great complication in the fittings. Again, when shafting is used, the instrument to be driven must be placed opposite a pulley on the shaft; in the arrangement about to be described, the instrument may be moved to any part of the tables, and the tables can be fixed in any part of the rooms.

We will now describe in detail the arrangement as applied in the Laboratory at Cambridge. The motor is an Otto gas-engine. It was found most convenient to place it in the cellar.

In Fig. 1 a pulley, B, fixed to a short length of shafting, is driven by a cord from the fly-wheel of the gas-engine, shown at A. The small pulleys at C are necessary to guide the cord in the required direction. This direction is vertical, hence no sag can compensate for changes of length due to stretching and the varying moisture of the atmosphere. The following arrangement was therefore adopted. Two grooves are turned in the pulley B, over which the cord passes twice, having between the first and second time passed under a pulley which supports a weight, W. Thus, the only effect of a change of length in the cord is to raise or lower the weight.

The short length of shafting driven in this manner by the pulley B is used to distribute the power to various rooms. A cord runs to each room, and forms a separate system, which can be stopped or started independently. This is done in the following manner. Fig. 2 shows a side view of the shafting, to which a number of pulleys are fixed. One of these, E, drives a second pulley, F, which is supported by a frame turning about a pivot, G. The pulley F has three grooves in it. A short leather band passes round the centre groove and round the pulley E; thus, if the centres of the pulleys E and F are brought together, the leather band which receives its motion from E will slip round F without driving it; but on the other hand, if the centres are pulled apart, F will be driven. When the cord H is pulled, the centres are brought together, and when released, a weight, K, gives the necessary

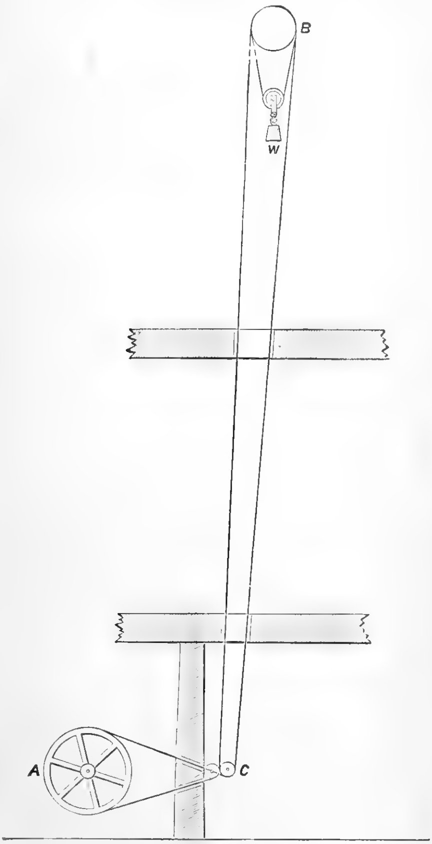

FIG. 1.

tension to the leather band. The endless cord L, which conveys power to one of the various rooms, is driven by the pulley F. This arrangement is something like that adopted for connecting the fly-wheel of the gas-engine with the shafting. The cord L first passes three-quarters of a turn round one of the grooves in the pulley F, under the pulley, M, which supports the weight K, and a quarter of a turn round the other groove of the pulley F. The cord then passes away in a horizontal direction, and is guided by pulleys round angles, either in a vertical or horizontal plane, to the rooms where the power is required. It is then guided in the same manner along the edge of each of the tables on which the instruments are to stand. The weight K, besides giving the necessary tension to the leather band, will take up all slack in the cord L. The cord runs near the ceiling, and is either led over pulleys and down to the tables in the rooms, or up through the ceiling to tables standing on the floor above.

The power is transmitted as follows to the instruments standing on the table from the cord running along its edge. Fig. 3 shows a piece of apparatus designed for this purpose, which has been called a driving-pulley. It is clamped to the edge of the table, and the cord is then made to pass round the pulley, P, as shown. This has the effect of raising the weight K, Fig. 2. The instruments are driven by a light cotton band passing round one of two grooves in a pulley fixed to the same spindle as the pulley P. The larger of the grooves is shown at Q, the smaller is not visible in the figure. The band is kept tight by means of a pulley and a weight, in the manner previously described; this arrangement also allows the

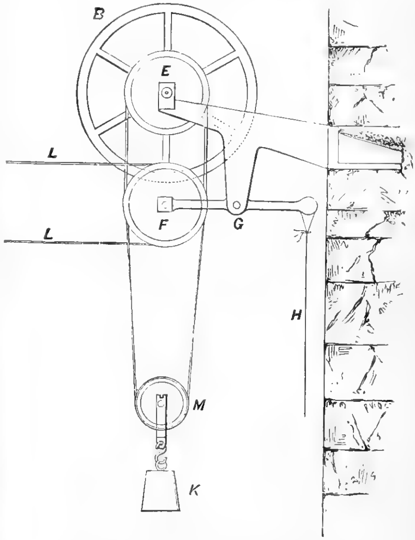

FIG. 2.

instrument to be moved to any distance from the driving pulley without altering the length of the band.

In the figure, the instrument being driven is shown at R. It is essential that it may be stopped without interfering with the cord which supplies power to the room. This is done in the following manner, which we believe is new. The handle T is fixed to a brass piece formed in the shape of a sector of a pulley, with an overhanging edge. It is arranged to turn about the bearing through which the spindle of the pulley Q passes, and can therefore rotate about the same axis as this pulley. The groove in the overhanging edge is in a line with the groove in the pulley. In the figure the cotton band is shown resting in this groove, and not in the groove of the pulley Q; now, if the sector is turned through half a revolution by the handle T, the cotton band will fall from it into the groove in the pulley Q. Thus the instrument is started; the reverse action not only throws it out of gear, but the friction of the cord running in the groove in the sector acts as a brake, and brings it quickly to rest. From the foregoing description it is evident that, once moved, the sector is required to remain in that position until moved again; in fact, it must turn with a certain amount of stiffness. A short piece of cord lies in a groove cut in its edge as shown at S; as the cord is prevented from moving and kept in tension by an india-rubber band, its friction in the groove must be overcome when the sector is turned. The smaller of the two grooves on the pulley Q is not visible in the figure, neither is the arrangement shown for lifting the cotton band out of this groove. The instrument being driven is a rotating cylinder for recording any vertical movements in the ordinary manner. Five grooves of different sizes are cut in the pulley R, and, as there are two grooves in the pulley Q, ten different speeds are possible. The sizes of these pulleys are such that the ten speeds form a geometrical series in which two consecutive speeds are in the ratio of 100 : 140.

The cotton band as well as the main driving-cord can be slipped off the driving-pulley without being cut; it can then at once be removed from the table. From this description it will be seen how the instruments may be driven, as before stated, whilst standing on any part of the table.

This method of distributing power is convenient for

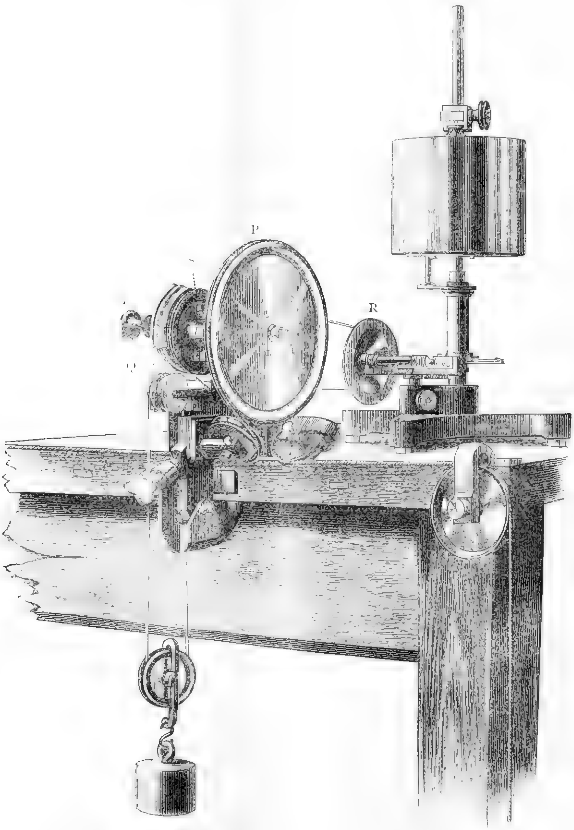

Fig. 3.

laboratories where a large amount of class-work is done, as it removes the necessity of supplying each student with a separate instrument containing clockwork. It is also most useful in original work for driving special pieces of apparatus which may often require more power than can be obtained by clockwork.

Cotton has been found to be the best material for the cords; it has the advantage of running almost silently, and is very durable. The pulleys that guide the cord from the shaft to the various rooms have been designed to run a long time without requiring oil, and with very little friction. The speed adopted is 10 feet per second; a small cord running at this speed can easily do all the work that is required.

A great variety of instruments are driven in the laboratory at Cambridge; among others we may mention a turning-lathe, also a small centrifugal machine which runs at about ninety turns per second, requiring a special driving-pulley.

The whole apparatus, both at Manchester and at Cambridge, has been designed and constructed by the Cambridge Scientific Instrument Company.

RADIANT LIGHT AND HEAT[1]

IV. (*Continued*)

Radiation and Absorption—Celestial Applications

THIS is perhaps the most suitable place for alluding to a method of obtaining a picture of the corona on ordinary occasions, recently introduced by Dr. Huggins, and which has already met with considerable success.

By using a suitable absorbing medium Huggins has been able so greatly to diminish the proportion between the terrestrial glare and the light from the corona, that a photographic image of the regions around the sun exhibits visible traces of an excess of action in certain places which are probably those occupied by the corona. Plates prepared in this manner were compared with those taken of the corona in Egypt during a total eclipse, and the comparison, made by several observers, appears to leave little doubt that the object photographed is really the corona. A development of this method would prove a great boon to solar inquiry.

Another result of the application of the spectroscope to the sun has been the determination of the rates of motion of the currents which take place in the solar atmosphere.

This is done by the method of displacement already mentioned, a motion of solar gas towards the eye pushing its spectral lines to the more refrangible side of their ordinary position, while a motion in the opposite direction has a contrary effect. In Fig. 20 we have a representation of the deviation of the F line in a spot spectrum.

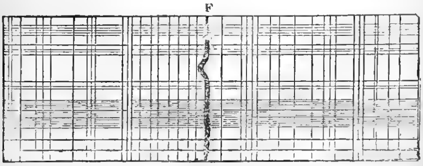

FIG. 20.

By this means prodigious solar velocities have been observed. In our earth when air moves at the rate of 100 miles an hour we count it a hurricane, but in the sun we find gaseous matter frequently moving at the rate of 100 miles a second.

It has likewise been observed that the velocities of solar motions are greatest on occasions of maximum sun spots, when there appears to be a general increase in the activity of all things belonging to our luminary.

It may therefore be said that all our observations combine in proving how extensive the solar atmosphere must be, and how enormous must be the velocities of its constituents, and more especially of the hydrogen, which enters largely into its composition.

We have thus two facts connected with our luminary which fill us with amazement. For we have, in the first place, his continued ability to radiate powerfully without cessation, or even apparent diminution, and we have, in the second, the astounding velocities of his atmospheric motions.

A little reflection will, however, serve to convince us that these two wonderful facts are intimately connected together and serve to explain each other, and that in truth the atmospheric motions are the very machinery which enables the sun to continue his radiation.

For let us inquire what is the essential condition of such continued radiation.

Clearly we must have some process by which there shall be a continuous and very rapid stream of fresh particles sent to the surface of the sun. These are there required to give out their light and heat, and then promptly to retire, being replaced by fresh particles from beneath, which again in their turn give out light and heat and then rapidly retire. It is necessary that there should be some powerful machinery of this kind, in virtue of which fresh recruits shall continually be carried to the front, while the exhausted battalions are promptly marched behind into the magazine.

Now such machinery is supplied in the vast and intense solar convection currents by means of which the cold matter from above is rapidly carried down, forming a sun spot, while the hot matter from beneath is rapidly carried upwards, forming a facula.

This ceaseless system of ascending and descending currents gives rise, no doubt, to the mottled appearance of our luminary, while in certain districts of the sun and on certain occasions the system is swelled out into gigantic proportions, and we have a large sun spot, with its accompanying faculæ. Nor is it difficult to understand why convection currents should be so powerful in the atmosphere of our luminary. The intensity of such currents will depend upon the following conditions:—

(1) On the intensity of the heat of the hot portions of the arrangement as compared to that of the cold.

(2) On the intensity of gravity.

(3) On the scale of the whole arrangement.

(4) On the presence of condensible substances in the atmosphere.

Now in the sun the heat of the hot particles is very great, while the space around the sun may be taken to represent something without heat. Again the intensity of gravity at the sun's surface is very great, being about twenty-eight times greater than that with which we are familiar on the earth.

In the third place, the scale of the whole arrangement is very great; and, lastly, we have without doubt the presence of condensible substances in the solar atmosphere. All these are powerful causes, and we must bear in mind that they have not merely to be added, but rather multiplied together. Can we therefore wonder that their joint effect is such as to raise the violence of solar storms into something like 60 or 100 miles per second?

These considerations may likewise, perhaps, serve to throw light on the question of solar variability. We have seen that sun spots have a period of eleven years, and that near the minimum of this period there are occasions when the sun is entirely without spots.

Now it is sufficiently obvious, and has likewise been proved experimentally, that a sun spot gives out less light and heat than the ordinary solar surface. On the other hand, the proportion which the spotted area bears to that of the whole disc is insignificant, so that, taking these two facts together, we should at first sight imagine that the sun ought to give us very slightly less light and heat on those occasions when there are most spots.

I think, however, that this direct action is probably inappreciable, and that sun spots are rather to be regarded as *symptoms* of a particular state of the sun, implying an increased activity of solar convection currents. Now, inasmuch as the outpouring of solar light and heat is kept up by means of these convection currents, we might therefore expect that on occasions when such currents are peculiarly powerful the sun should give out most light and heat. To use the words of the late Sir J. Herschel, the "*sun pot*" may on such occasions be boiling very rapidly.

On the whole, therefore, theory would lead us to infer that the sun will be found most powerful in its radiation on those occasions when it has most spots on its surface. It will, however, be noticed that this is merely a theoretical conclusion, and has to be supported by evidence which must of course be terrestrial. Have we, then, any terrestrial evidence that the sun is more powerful in its

[1] Continued from p. 38.

radiation at times of maximum than at times of minimum sun spot frequency?

In reply to this question, we must acknowledge that of direct evidence derived from the actinometer we have hardly any. Certain preliminary observations made by Mr. Hennessey at the headquarters of the Trigonometrical Survey in India may perhaps induce us to imagine that the sun may be most powerful on occasions of maximum sun spot frequency, but this is far from conclusive. We have, however, very strong indirect evidence in favour of this conclusion. This is derived partly from the facts of terrestrial magnetism and partly from those of terrestrial meteorology, that from the former being the stronger of the two. It is well known that the sun produces changes in the magnetism of the earth. It gives rise, for instance, to the solar-diurnal variation of the needle which is a systematic change; and it likewise produces magnetic storms, these words being employed to denote changes of a peculiarly abrupt and irregular kind. Now undoubtedly these both imply an energetic action of some kind on the part of the sun, and we have strong grounds for supposing that this energetic action is connected with the radiating power of our luminary. But both of these solar actions upon the magnetism of the earth are decidedly stronger in times of maximum than in times of minimum sun spot frequency.

Such electrical phenomena as the aurora borealis and the currents which take place in the crust of the earth are likewise peculiarly developed on the same occasions.

In Fig. 21 we have a diagram representing the connection between sun spot maxima, the maxima of declination range, and the frequency of the aurora borealis.

When we come to meteorology, the evidence before us is not so conclusive, although here also what we have tends, I think, in the same direction. Mr. Meldrum has shown that there are most cyclones in the Indian Ocean

SOLAR SPOTS, MAGNETIC DECLINATION, AND AURORAL DISPLAYS.

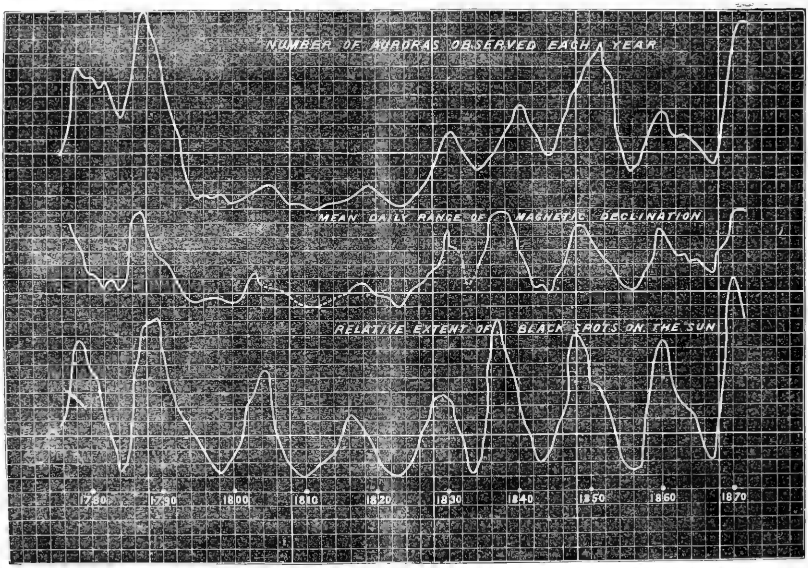

FIG. 21.

about times of maximum sun spots, and M. Pöey has proved the same thing with respect to West Indian hurricanes. On the whole, too, and in the majority of stations, the rainfall is greatest on the same occasions.

Again, let us take the barometric pressure of the air. Here a little reflection will convince us that the peculiar variations in the distribution of such pressure are really caused by the sun. For instance, we know that Western Siberia during the winter season has a pressure decidedly above the average, and we should therefore imagine that in years when the sun is peculiarly powerful the winter pressure in Siberia would prove to be particularly high. Now this is just the state of things which Mr. Blanford has found to correspond with years of maximum sun spot frequency, and thus the evidence is in favour of these being also years of maximum solar power. The Indian meteorologists have derived similar conclusions from the observations made in India. In fine, we may, with the balance of probability in our favour, adopt the conclusion deduced by Mr. Baxendell at a comparatively early period, who found that the forces which produce the movements of the atmosphere were apparently more energetic in years near maximum than in years near minimum sun spot frequency.

Let me now proceed to indicate the nature of the information which the spectroscope gives us regarding the planets and comets of our system. Since the moon and the various planets are illuminated by the sun, their spectra will necessarily be built upon that of the sun. As a matter of fact, this is found to be the case; but we ought to bear in mind that the solar rays that reach us from a planet must have penetrated some distance into the atmosphere of that planet. In doing so they will most probably have suffered spectral absorption, the nature of which may thus suffice to throw light upon the constitution of the planet's atmosphere.

Working in this manner, Dr. Huggins has observed no trace of an atmosphere in the moon, but in the spectrum of Jupiter lines are seen which indicate the existence of an absorbing atmosphere. One band appears to correspond in spectral position with dark lines due to our earth's atmosphere; but another band is different from

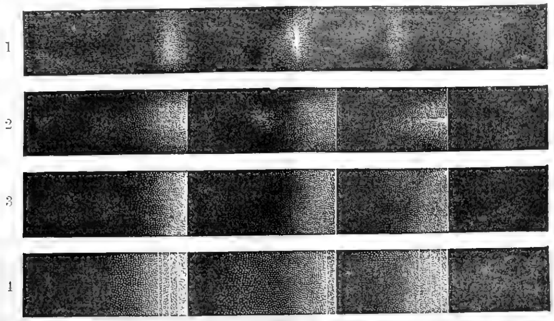

Fig. 22.—(1) Spectrum of Brorsen's comet; (2) Spectrum of Winnecke's comet; (3) Spectrum of carbon in olefiant gas; (4) Spectrum of carbon in olive oil (Huggins).

any line caused by our atmosphere, and indicates most probably the existence of some unknown constituent. Saturn has likewise a band common to the earth, so that aqueous vapour probably exists in the atmospheres of Jupiter and Saturn.

The spectrum of Mars indicates in like manner the

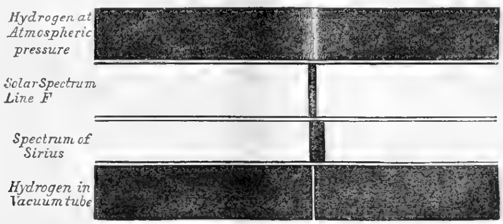

Fig. 23.

existence in the atmosphere of that planet of matter similar to that which occurs in the earth's atmosphere.

The absorption spectra of the far distant planets have likewise been examined.

Padre Secchi and M. Janssen agree with the conclusion that the vapour of water probably exists in certain planetary atmospheres.

In the absorption spectrum of our atmosphere Professor

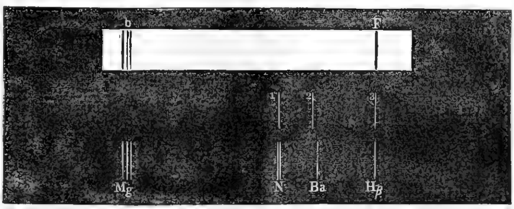

Fig. 24.—First, the solar spectrum; next, the spectrum of the nebulæ; 1, 2, 3 the lines observed. Below, the bright lines of magnesium, nitrogen, barium, and hydrogen.

Piazzi-Smyth[2] has noticed a band which appears to be associated with the presence or possibility of rain, and which he has termed the rain-band. Strangely enough in the bright spectrum of the aurora borealis, which comes from our atmosphere, there is a line which we cannot identify with the spectrum of any known terrestrial substance.

Dr. Huggins has likewise studied the spectra given by the brighter portions of comets, and has obtained for many of these bodies lines which resemble the spectrum of carbon, as taken in a hydrocarbon.

In Fig. 22 we have, first, the spectrum of Brorsen's comet; secondly, the spectrum of Winnecke's comet; thirdly, the spectrum of carbon in olefiant gas; fourthly, that of carbon in olive oil.

More recently the same observer has found other specimens of this class of bodies, which give spectra essentially different from the hydrocarbon type, and he remarks that as the meteors which come down to us differ greatly in chemical constitution, so it is not surprising that a similar difference should be found in comets which we know to be very closely allied to meteors.

Dr. Miller and Mr. Huggins were amongst the first to give us information regarding the spectra of stars. These bodies exhibit spectra very similar to that of the sun—that is to say, they give us an underlying continuous spectrum, intersected with dark lines. We have thus evidence of a similarity in physical constitution between our sun and these very distant bodies.

The position of the dark lines is the great object of interest in stellar spectra, and by the method already described the presence of various terrestrial elements has been detected in the stars.

In the most brilliant bluish-white stars, along with the presence of numerous fine lines, we have a comparatively small number of prominent absorption lines, the substances which these indicate as present being hydrogen, calcium, magnesium, and sodium. We shall return to this subject on a future occasion.

Miller and Huggins were so fortunate as to obtain the spectrum of a star which suddenly blazed out in May, 1866, and found in it the unmistakeable presence of bright hydrogen lines.

Such a star is probably to be regarded as exhibiting on an enormous scale the same phenomenon which is frequently seen in the outburst of hydrogen from the interior of our luminary. Indeed, we have sometimes bright lines of hydrogen in the spectrum of certain solar regions. Padre Secchi has also ascertained that several very small stars exhibit bright lines.

I need hardly say that in the case of the fixed stars where the disc is a mere point, we have no possibility of differentiating between various portions of it, or of ascertaining the velocities of its atmospheric motions by spectral displacement.

We have, however, the means of ascertaining by this method whether the star be approaching us or receding from us, and how rapidly it is doing so. Huggins has made many laborious and interesting observations of this nature, and has determined the relative motion to or from us of many stars—a result which could not possibly be ascertained without the spectroscope.

In Fig. 23 we have an indication of the proper motion of Sirius as seen by the displacement of the hydrogen line F in the spectrum of that star.

Before concluding this branch of my subject, let me briefly allude to the light thrown by spectrum analysis on the composition of certain of the nebulæ. On directing his stellar spectroscope to the planetary nebula in the constellation Draco on 20th August, 1864, Dr. Huggins found that its spectrum consisted of three bright lines on a dark background—in fine, that it was the spectrum of incandescent gas.

Of these three lines one is in all probability the hydrogen line H; another appears to coincide with one of the lines of nitrogen, while the third does not coincide with any known line.

Other nebulæ have since been found by Huggins to give us similar spectra.

Fig. 24 denotes the general spectrum given by the nebulæ.

It thus appears that we have already derived great information regarding the constitution of the heavenly bodies by means of spectrum analysis.

BALFOUR STEWART

(*To be continued.*)

NOTES

THE death is announced, in his seventy-first year, of Dr. John Christopher Draper, Professor of Chemistry in the Medica Department of the University of the City of New York. Dr. Draper was the eldest son of the eminent Prof. John W. Draper. His scientific papers, apart from those on the science of medicine, are devoted to chemical and physical subjects; and among the latter chiefly to optical phenomena. His last one, relating to dark lines in the solar spectrum, attracted some attention at the time, 1878-79.

THE death is announced of Mr. James Fergusson, F.R.S., on the 9th inst., at the age of seventy-eight years. Mr. Fergusson was well known by his writings on Indian architecture, and also by his magnificent work on "Tree and Serpent Worship in India."

THE deaths among French Academicians have been unusually numerous of late; we have to record this week that of M. de Saint-Venant, a member of the Section of Geometry.

THE Russian Academy of Science has elected Mr. David Gill, Astronomer-Royal at the Cape of Good Hope, a Corresponding Member.

SEVERAL French papers have published articles on the opportunity of celebrating the centenary of Arago's birth, this celebrated astronomer and physicist having been born at Estagel, a country town of the Department of the Pyrénées Orientales, on Feb. 26, 1786. As he was a Copley Medallist and a foreign member of the Royal Society of London, it is expected that this Society will be invited to send a delegate to take part in the proceedings. Arago was elected a member of the Paris Academy at the early age of twenty-three, after having achieved the measurement of the meridian arc from Dunkirk to Formentera, for determining the length of the metre. His predecessor was Jerome de Lalande. In 1830 he was elected Perpetual Secretary, and he continued to act as such during twenty-three years up to his death, which took place in 1853. His works have been edited by Barral, and fill seventeen large octavo volumes, of which four are devoted to "Astronomie Populaire."

IN a very excellent article in *Science* on "The Government and its Scientific Bureaus," we find some wholesome remarks on the conditions under which scientific work can be performed at its best. "Science cannot be carried forward by prescribing too definitely the tasks of scientific men. They may be bound by appointed days and hours; they may be told to perform specific duties,—and if only the maintenance of routine work is required, such regulations may secure fidelity and efficiency. But if knowledge is to be advanced, if better methods of work are to be discovered, if greater accuracy is desired, if unknown facts are to be ascertained and recorded and discussed, and, in short, if there is to be real progress, the methods of freedom are to be employed, not those of petty regulation. By this we mean that if the great undertakings which the Government has in charge, if especially its surveys of the coast and of the interior are to go forward, discretion must be given to the chiefs of bureaus, and they must be held to accountability for the aggregate success of their work. Honesty, economy, clear and accurate statement of accounts are, of course, to be demanded in every office: nobody questions this. But the determination of what shall be undertaken in a given year, to whom it shall be assigned, what allowances shall be made for instruments, books, and assistants, —these are questions which experience and judgment must decide. Somebody who has all the facts in mind must make the determination, and he must not be too quickly condemned, because the immediate results of the investigations which he has undertaken are not yet apparent. The highest personal character should be found in every one who is called upon to direct the labours of a scientific corps; he should be faithful, watchful, careful that all the interests intrusted to him may be promoted; but he should be free within the limitations of his office to select his subordinates, determine their duties, and prescribe their methods. Only by such regulated freedom as this can the highest results be obtained. Discretion with responsibility, in all the higher work of science, will bring the best services from those whose moral attitude is what it should be: no others should be intrusted with the leadership."

FROM the "Washington Letter" of *Science* we learn that in the retiring address of the President of the Chemical Society there Prof. F. W. Clarke gave "an able and entertaining *résumé* of the growth of chemistry in Washington during the past twelve or fifteen years." The President concluded with a plea for the establishment of a national laboratory, which, in its dimensions and equipment, should be commensurate with the importance and dignity of the science. Arguments to show the economy in, and the necessity for, such an establishment were not lacking, either in number or force. Examples of duplication or useless repetition of work, multiplication of instruments and facilities with no increase in efficiency, and frittering away time and energy on work properly belonging elsewhere, were given with a convincing emphasis, which made it a little difficult, at the close of the address, to believe that there were two sides to the question.

THE programme of the Congress of French Learned Societies for 1886 has been declared by a decree published by the Minister of Public Instruction. Amongst other subjects to be discussed by the fifth, or Natural Sciences Section, we find the following:—Study of the topographical distribution of the species inhabiting the French coasts; detailed study of the fluviatile fauna of France, indicating the species which are migratory and those which are permanent, and in the former case the dates of arrival and departure, noting also the time of laying the eggs, and the influence of the composition of the water; study of the migrations of birds, and of the periodical phenomena of vegetation, noting the coincidences of budding, flower, and maturity, with the appearance of the principal kinds of insects injurious to agriculture; the influence of winter temperatures on insects and their duration; study of honey- and wax-producing insects; a study, from an anthropological point of view, of the different populations which have occupied, in whole or part, a certain part of France since the most remote times; the course and duration of the great epidemics of the Middle Ages and of recent times; a comparison between the Tertiary vertebrates of the various French formations in view of the successive modifications which the types have undergone; a comparison of the Quaternary vertebrates with similar species of the present epoch; a comparison of the flora of the southern departments of France with that of Algiers; the Eucalyptus and its uses; the influence of the chain of the Cevennes in the propagation northwards of the Mediterranean species of plants and animals; a study of the general movements of sand in Asia and Africa, noting the region in which it is retreating and that in which it is advancing.

WE lately commented on a suggestion made, on economical grounds, that Jamaica should diminish the amount spent on, and by consequence the usefulness of, the Colonial Botanic Gardens. We are pleased to notice that similar views do not prevail elsewhere in the West Indian Islands, for at a late meeting of the Legislative Council of Grenada, the Governor announced that it had been decided to establish a Botanic Garden on the island. The site, he said, was selected on Government land, and an annual grant of 300*l.* was placed on the estimates for the expense of preparing the ground and paying a superintendent, who has not yet been engaged. The sum appears small, but is really a considerable amount for an island which is small and far from wealthy.

MESSRS. WODDERSPOON AND CO., Serle Street, Lincoln's Inn, are publishing in one sheet on paper for sixpence, an easy guide to the principal constellations and stars visible in Great Britain. We have first a map of the circumpolar stars, and another showing those north and south of the equator; the guiding lines, by which the stars can be easily found from the instructions carefully given, being printed in red ink. It is very clear that the author has embodied in this cheap chart the results of much labour for the teaching of people uninstructed in such matters. We learn, indeed, that many copies have already been given away among coastguardsmen, labourers, and others, who, after a little instruction, use them greedily, and delight in having them to refer to. This is distinctly a good work, and we trust that some of our readers will follow it up.

WE hear that the reconstruction of the Naval Astronomical Observatory of Japan, which has been deferred for several years owing to the extraordinary outlay required, is to be commenced at once according to the plans originally prepared.

IT is stated that M. Paul Bert, the French physiologist, has been appointed Resident in Annam, Tonquin, and Cambodia.

A COMPLETE set of observations of the new star in Orion discovered by Mr. J. E. Gore on December 13, 1885, was, *Science* states, obtained at Harvard College Observatory on December 16—the very evening on which the despatch was received from Lord Crawford—settling the non-identity of the star with D.M. + 20°, 1172, the star named in the despatch. A meridian circle observation by Prof. Rogers gave for the position of the *nova* R.A. 5h. 49m. 4·25s., Decl. + 20° 9′ 15″·6. Prof. Pickering's photometric measures made the magnitude 6·2, and the spectroscope showed the existence of bright bands. Two excellent photographs fixing the position of the star with reference to neighbouring stars were obtained, and one photograph of the spectrum. The indications are suggestive of the new star being a long-period variable, and there was a slight suspicion of a diminution in magnitude during the first six or seven hours it was under observation.

MR. WOOD-MASON has, it is stated, undertaken to prosecute a thorough inquiry into the silk-producing larvæ of India.

SOUTH-EASTERN ROUMELIA was visited on the evening of the 8th and morning of the 9th inst. by earthquake shocks, some of which were of a violent character. At Philippopolis the movement is described as being in a south-south-easterly direction.

ON December 29, 1885, there was an earthquake at Ismidt, in Asia Minor, not far from Constantinople. It took place at half-past one in the afternoon. The oscillations were slight, and passed from west to east.

AN interesting discovery of bronze hatchets and other prehistoric warlike instruments has been made at Llanwitt Major, Glamorganshire. As a number of workmen were engaged in digging a foundation for a building, they discovered three spear-heads, six hatchet-like celts, and several other interesting relics, which were concealed under an ancient wall. Some bones were also found. A further search is being organised.

SOME interest is being excited among geologists in Kent by the great depth to which a boring has been sunk at the Dover Guard Prison for a water supply. The boring, which is close to the sea, has now reached a depth of 1000 feet, being 700 feet below the sea-level.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mr. T. Risely Griffith; a Gray Ichneumon (*Herpestes griseus*) from India, presented by Capt. J. Cutting; a Gray Squirrel (*Sciurus cinereus*) from North America, presented by Mrs. Charles Neck; a Golden Eagle (*Aquila chrysaetos*), European, presented by Mr. H. V. Knox; a Bronze-winged Pigeon (*Phaps chalcoptera*) from Australia, presented by Mr. Augustus F. Spry; a —— Hangnest (*Xanthosomus icterocephalus*) from Venezuela, a Song Thrush (*Turdus musicus*), British, deposited; a White-thighed Colobus (*Colobus vellerosus*), a Moustache Monkey (*Cercopithecus cephus*), a Ludio Monkey (*Cercopithecus ludio*) from West Africa, received in exchange.

OUR ASTRONOMICAL COLUMN

THE LEYDEN OBSERVATORY.—Prof. H. G. van de Sande Bakhuyzen has published his Report for the year ending September 15, 1885. The work to which the meridian circle was devoted during the year was the continuation of the observation of a selected list of fairly bright stars situated in the immediate neighbourhood of the Pole. It is expected that this series of observations will be finished off during the present winter. With the 7-inch refractor, nine observations of Wolf's comet were made. Between October 1884 and March 1885, a series of measures have been made with Airy's double-image micrometer attached to this equatorial, for the purpose of determining the systematic errors of the measures of the diameters of Mars and Uranus obtained in former years. For this purpose, Prof. Bakhuyzen has measured the diameters of artificial disks, formed by circular holes in a copper plate, made so as to resemble, both in size and brightness, the planets themselves. The results of these investigations will be published shortly. The reduction of the meridian observations, 1877-85, is in a forward state, some parts being nearly completed. This work is intrusted to Dr. E. F. van de Sande Bakhuyzen, the First Observer. Some progress has also been made in the reduction of the zone observations, 1874-76. Prof. Bakhuyzen himself has been chiefly occupied with his monograph on the rotation-period of Mars, now published. In March 1885 work was commenced in connection with the erection of the new $10\frac{1}{2}$-inch objective, and the instrument is now ready for use. The mounting has been supplied by the Repsolds, and the object-glass by Alvan Clark and Sons. Its performance, so far as it has yet been tested, appears to be remarkably good, and does not compare unfavourably with that of other instruments of similar size. In Prof. Bakhuyzens' hands it will doubtless do good work.

FABRY'S COMET.—Dr. H. Oppenheim gives the following ephemeris for this comet for Berlin midnight:—

1886	R.A. h. m. s.	Decl. ° ′	Log Δ	Log *r*
Jan. 17	23 31 4	+21 53·4	0·2304	0·2025
19	23 29 58	22 5·3		
21	23 28 58	22 18·2	0·2316	0·1857
23	23 28 3	22 32·1		
25	23 27 14	22 46·9	0·2319	0·1682

BROOKS'S COMET.—The following elements and ephemeris have been computed for this comet by Dr. J. Palisa:—

$$T = 1885 \text{ Nov. } 28{\cdot}2436 \text{ Berlin M.T.}$$

$$\left.\begin{aligned} \pi &= 301°\ 29'\ 50'' \\ \Omega &= 262\ 30\ 48 \\ i &= 42\ 31\ 27 \end{aligned}\right\} \text{Mean Eq. } 1886{\cdot}0.$$

$$\log q = 0{\cdot}04091$$

Error of the middle place (O – C).

$$d\lambda \cos\beta = +4''{\cdot}7 \qquad d\beta = 4''{\cdot}5$$

Ephemeris for Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log. Δ	Log. *r*	Brightness.
Jan. 14	21 5 25	+12 8·6	0·2921	0·1261	0·74
18	21 20 46	13 48·6	0·2989	0·1377	0·68
22	21 35 48	15 25·2	0·3064	0·1495	0·62
26	21 50 48	+16 57·4	0·3146	0·1614	0·57

The brightness on December 28 is taken as unity.

BARNARD'S COMET.—For Barnard's comet Dr. H. Oppenheim gives the following ephemeris, also for Berlin midnight:—

1886	R.A. h. m. s.	Decl. ° ′	Log Δ	Log *r*
Jan. 17	2 37 45	+11 14·7	0·2136	0·3193
19	2 34 22	11 38·4		
21	2 31 8	12 2·5	0·2173	0·3068
23	2 28 4	12 27·0		
25	2 25 9	12 51·8	0·2213	0·2937

GORE'S NOVA ORIONIS.—Dr. Copeland, examining the spectrum of this object at Lord Crawford's Observatory, Dun Echt, finds distinct evidence of a spectrum of bright bands superposed on a well-marked spectrum of the third type; these bright bands corresponding to those ordinarily seen in cometary spectra, and obtained in the spectrum of a coal-gas flame.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 JANUARY 17–23

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 17

Sun rises, 8h. 0m.; souths, 12h. 10m. 24·5s.; sets, 16h. 21m.; decl. on meridian, 20° 42′ S.: Sidereal Time at Sunset, 0h. 9m.

Moon (Full on January 20) rises, 13h. 53m.; souths, 21h. 44m.; sets, 5h. 39m.*; decl. on meridian, 18° 13′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 40	10 36	14 32	22 59 S.

MR. AITKEN ON DEW[1]

THE first point referred to in this paper is the source of the vapour that condenses to form dew. A short historical sketch is given of the successive theories from time to time advanced on this point, showing how in early times dew was supposed to descend from the heavens, and then afterwards it was suggested that it rose from the earth, while Dr. Wells, who has justly been considered the great master of this

[1] Abstract of Paper read before the Royal Society of Edinburgh on December 21, 1885, communicated by permission of the Council of the Society.

subject, thought it came neither from above nor from below, but was condensed out of the air near the surface of the earth. He combated Gersten's idea that it rose from the earth, and showed that all the phenomena observed by Gersten and others which were advanced to support this theory could be equally well explained according to the theory that it was simply formed from the vapour present at the time in the air, and which had risen from the ground during the day, and concluded that if any did rise from the ground during night, the quantity must be small, but, with great caution, he adds that "he was not acquainted with any means of determining the proportion of this part to the whole."

A few observations of the temperature of the ground near the surface and of the air over it, first raised doubts as to the correctness of the now generally-received opinion that dew is formed of vapour existing at the time in the air. These observations, made at night, showed the ground at a short distance below the surface to be always hotter than the air over it; and it was thought that so long as this excess is sufficient to keep the temperature of the surface of the ground above the dew-point of the air, it will, if moist, give off vapour; and it will be this rising vapour that will condense on the grass and form dew, and not the vapour that was previously present in the air.

The first question to be determined was whether vapour does, or does not, rise from the ground on dewy nights. One method tried of testing this point was by placing over the grass, in an inverted position, shallow trays made of thin metal and painted. These trays were put over the ground to be tested after sunset and examined at night, and also next morning. It was expected that, if vapour was rising from the ground during dewy nights, it would be trapped inside the trays. The result in all the experiments was that the inside was dewed every night, and the grass inside was wetter than that outside. On some nights there was no dew outside the trays, and on all nights the inside deposit was heavier than the outside one.

An analysis of the action of these trays is given, and it is concluded that they act very much the same as if the air was quite still. Under these conditions vapour will rise from the ground so long as the vapour-tension on the surface of the ground is higher than that at the top of the grass, and much of this rising vapour is, under ordinary conditions, carried away by the passing air, and mixed with a large amount of dryer air, whereas the vapour rising under the trays is not so diluted; and hence, though only cooled to the same amount as the air outside, it yields a heavier deposit of dew.

Another method of testing this point was employed, which consisted in weighing a small area of the exposed surface of the ground, as it was evident that if the soil gave off vapour during a dewy night, it must lose weight. A small turf about 6 inches (152 mm.) square, was cut out of the lawn and placed in a small shallow pan of about the same size. The pan with its turf, after being carefully weighed, was put out on the lawn in the place where the turf had been cut. It was exposed for some hours while dew was forming, and on these occasions it was always found to lose weight. It was thus evident that vapour was rising from the ground while dew was forming, and therefore the dew found on the grass was formed of part of the rising vapour, trapped or held back by coming into contact with the cold blades of grass.

The difference between these experiments in which the exposed bodies *lose* weight, and the well-known ones in which bodies are exposed to radiation, and the amount of dew formed is estimated by the *increase* in their weight, is pointed out. In the former case the bodies are in good heat-communication with the ground, whereas in the latter, little or no heat is received by conduction from the earth.

Another method employed for determining whether the conditions found in nature were favourable for dew rising from the ground on dewy nights, was by observations of the temperatures indicated by two thermometers, one placed on the surface of the grass, and the other under the surface, amongst the stems, but on the top of the soil. The difference in the readings of these two thermometers on dewy nights was found to be very considerable. From 10° to 18° F. was frequently observed. A minimum thermometer placed on, and another under, the grass, showed that during the whole night a considerable difference was always maintained. As a result of this difference of temperature, it is evident that vapour will rise from the hotter soil underneath, into the colder air above, and some of it will be trapped by coming into contact with the cold grass.

While the experiments were being conducted on grass land, parallel observations were made on bare soil. Over soil the inverted traps collected more dew inside them than those over grass. A small area of soil was spread over a shallow pan, and after being weighed was exposed at the place where the soil had been taken out, to see if bare soil as well as grass lost weight during dewy nights. The result was that on all nights on which the tests were made the soil lost weight, and lost very nearly the same amount as the grass land.

Another method employed of testing whether vapour is rising from bare soil, or is being condensed upon it, consisted in placing on the soil, and in good contact with it, small pieces of black mirror, or any substance having a surface that shows dewing easily. In this way a small area of the surface of the earth is converted into a hygroscope, and these test-surfaces tell us whether the ground is cooled to the dew-point or not. So long as they remain clear and undewed, the surface of the soil is hotter than the dew-point, and vapour is being given off, while if they get dewed, the soil will also be condensing vapour. On all nights observed, these test-surfaces kept clear, and showed the soil to be always giving off vapour.

All these different methods of testing point to the conclusion that during dewy nights, in this climate, vapour is constantly being given off from grass-land, and almost always from bare soil; that the tide of vapour almost always sets outwards from the earth, and but rarely ebbs, save after being condensed to cloud and rain, or on those rarer occasions on which, after the earth has got greatly cooled, a warm moist air blows over it. The results of some of the experiments are given, showing, from weighings, the amount of vapour lost by the soil at night, and also the heat lost by the surface soil.

It seems probable that when the radiation is strong, that soil, especially if it is loose and not in good heat-communication with the ground, will get cooled below the dew-point, and have vapour condensed upon it. On some occasions the soil certainly got wetter on the surface, but the question still remains, Whence the vapour? Came it from the air, or from the soil underneath? The latter seems the more probable source: the vapour rising from the hot soil underneath will be trapped by the cold surface-soil, in the same way as it is trapped by grass over grass-land. During frost, opportunities are afforded of studying this point in a satisfactory manner, as the trapped vapour keeps its place where it is condensed. On these occasions the under sides of the clods, at the surface of the soil, are found to be thickly covered with hoar-frost, while there is little on their upper or exposed surfaces, showing that the vapour condensed on the surface-soil has come from below.

The next division of the subject is on dew on roads. It is generally said that dew forms copiously on grass, while none is deposited on roads, because grass is a good radiator and cools quicker, and cools more, than the surface of a road. It is shown that the above statement is wrong, and that dew really does form abundantly on roads, and that the reason it has not been observed is that it has not been sought for at the correct place. We are not entitled to expect to find dew on the surface of roads as on the surface of grass, because stones are good conductors of heat, and, the vapour-tension being higher underneath than above the stones, the result is, the rising vapour gets condensed on the under sides of the stones. If a road is examined on a dewy night, and the gravel turned up, the under sides of the stones are found to be dripping wet.

Another reason why no dew forms on the surface of roads is that the stones, being fair conductors, and in heat-communication with the ground, the temperature of the surface of the road is, from observations taken on several occasions, higher than that of the surface of the grass alongside. The air in contact with the stones is, therefore, not cooled so much as that in contact with the grass.

For studying the formation of dew on roads, slates were found to be useful. One slate was placed over a gravelly part of the road, and another over a hard dry part. Examined on dewy nights the under sides of these slates were always found to be dripping wet, while their upper surfaces, and the ground all round, were quite dry.

The importance of the heat communicated from the ground is illustrated by a simple experiment with two slates or two iron weights, one of them being placed on the ground, either on grass or on bare soil, and the other elevated a few inches above the surface. The one resting on the ground, and in heat-communication with it, is found always to keep dry on dewy nights, whereas the elevated one gets dewed all over.

The effect of wind in preventing the formation of dew is referred to. It is shown that, in addition to the other ways already known, wind hinders the formation of dew by preventing an accumulation of moist air near the surface of the ground.

An examination of the different forms of vegetation was made on dewy nights. It was soon evident that something else than radiation and condensation was at work to produce the varied appearances then seen on plants. Some kinds of plants were found to be wet, while others of a different kind, and growing close to them, were dry, and even on the same plant some branches were wet, whilst others were dry. The examination of the leaf of a broccoli plant showed better than any other that the wetting was not what we might expect if it were dew. The surface of the leaf was not wet all over, and the amount of deposit on any part had no relation to its exposure to radiation, or access to moist air; but the moisture was collected in little drops, placed at short distances apart, along the very edge of the leaf. Closer examination showed that the position of these drops had a close relation to the structure of the leaf; they were all placed at the points where the veins in the leaf came to the outer edge, at once suggesting that these veins were the channels through which the liquid had been expelled. An examination of grass revealed a similar condition of matters: the moisture was not equally distributed over the blade, but was in drops attached to the tips of some of the blades. These drops, seen on vegetation on dewy nights, are therefore not dew at all, but are an effect of the vitality of the plant.

It is pointed out that the excretion of drops of liquid by plants is no new discovery, as it has been long well known, and the experiments of Dr. Moll on this subject are referred to; but what seems strange is that the relation of it to dew does not seem to have been recognised.

Some experiments were made on this subject in its relation to dew. Leaves of plants that had been seen to be wet on dewy nights were experimented on. They were connected by means of an india-rubber tube with a head of water of about 1 metre, and the leaf surrounded with saturated air. All were found to exude a watery liquid after being subjected to pressure for some hours, and a broccoli leaf got studded all along its edge with drops, and presented exactly the same appearance it did on dewy nights. A stem of grass was also found to exude at the tips of one or two blades when pressure was applied.

The question as to whether these drops are really exuded by the plant, or are produced in some other way, is considered. The tip of a blade of grass was put under conditions in which it could not extract moisture from the surrounding air, and, as the drop grew as rapidly under these conditions as did those on the unprotected blades, it is concluded that these drops are really exuded by the plant. Grass was found to get "dewed" in air not quite saturated.

On many nights no true dew is formed, and nothing but these exuded drops appear on the grass; and on all nights when vegetation is active, these drops appear before the true dew, and if the radiation is strong enough and the supply of vapour sufficient, true dew makes its appearance, and now the plants get equally wet all over, in the same manner as dead matter. The difference between true dew on grass, and these exuded drops, can be detected at a glance. The drops are always exuded at a point near the tip of the blade, and form a drop of some size, while true dew is distributed all over the blade. The exuded liquid forms a large diamond-like drop, while the dew coats the blade with a pearly lustre.

Towards the end of the paper the radiating powers of different surfaces at night is considered, and after a reference to some early experiments on this subject, the paper proceeds to describe some experiments made with the radiation-thermometer described by the author in a previous paper. When working with this instrument it is placed in a situation having a clear view of the sky all round, and is fixed at the same height as the ordinary thermometer-screen, which is worked along with it, the difference between the thermometer in the screen and the radiation-thermometer being observed. This difference in clear nights amounts to from 7° to 10°. By means of the radiation-thermometer the radiating powers of different surfaces were observed. Black and white cloths were found to radiate equally well; soil and grass were also almost exactly equal to each other. Lamp-black was equal to whitening. Sulphur was about 2/3rds of black paint, and polished tin about 1/7th of black paint. Snow in the shade on a bright day was at midday 7° colder than the air, while a black surface at the same time was only 4° colder. This difference diminished as the sun got lower, and at night both radiated almost equally well. In the concluding pages of the paper some less important subjects are considered.

TELESCOPIC SEARCH FOR THE TRANS-NEPTUNIAN PLANET[1]

IN the twentieth volume of the *American Journal of Science*, at page 225, I gave a preliminary account of my search, theoretic and practical, for the trans-Neptunian planet. I say *the* trans-Neptunian planet, because I regard the evidence of its existence as well-founded, and further, because, since the time when I was engaged upon this search, nothing has in the least weakened my entire conviction as to its existence in about that part of the sky assigned; while, as is well known, the independent researches in cometary perturbations by Prof. Forbes conducted him to a result identical with my own,—a coincidence not to be lightly set aside as pure accident.

That five years have elapsed since this coincidence was remarked, and the planet is still unfound, is not sufficient assurance to me that its existence is merely fanciful. In so far as I am informed, this spot of the sky has received very little scrutiny with telescopes competent to such a search; and most observers finding nothing would, I suspect, prefer not to announce their ineffective search.

The time has now come when this search can be profitably undertaken by any observer having the rare combination of time, enthusiasm, and the necessary appliances. Strongly marked developments in astronomical photography have been effected since this optical search was conducted; and the capacity of the modern dry-plate for the registry of the light of very faint stars makes the application of this method the shortest and surest way of detecting any such object. Nor is this purely an opinion of my own. But the required apparatus would be costly; and the instrument, together with the services of an astronomer and a photographer, would, for the time being, be necessarily devoted exclusively to the work. While, however, the photographic search might have to be ended with a negative result, in so far as the trans-Neptunian planet is concerned, there would still remain the series of photographic maps of the region explored, and these would be of incalculable service in the astronomy of the future.

In the latter part of the paper alluded to above, I stated the speculative basis upon which I restricted the stellar region to be examined; also the fact that between November of 1877 and March of 1878 I was engaged in a telescopic scrutiny of this region, employing the twenty-six-inch refractor of the Naval Observatory. For the purposes contemplated I had no hesitation in adopting the method of search whereby I expected to detect the planet by the contrast of its disk and light with the appearance of an average star of about the thirteenth magnitude. A power of 600 diameters was often employed, but the field of view of this eye-piece was so restricted that a power of 400 diameters had to be used most of the time. I say, too, that, "after the first few nights, I was surprised at the readiness with which my eye detected any variation from the average appearance of a star of a given faint magnitude: as a consequence whereof my observing-book contains a large stock of memoranda of suspected objects. My general plan with these was to observe with a sufficient degree of accuracy the position of all suspected objects. On the succeeding night of observation they were re-observed; and, at an interval of several weeks thereafter, the observation was again verified." Subjoined to the original observations are printed these verifications in heavy-faced type.

In conducting the search, the plans were several times varied in slight detail,—generally because experience with the work enabled me to make improvements in method. Usually I prepared every few days a new zone-chart the region of over which I was about to search; and these charts, while containing memoranda of all the instrumental data which could be prepared beforehand, were likewise so adjusted with reference to the opposition-time of the planet as to avoid, if possible, its stationary point. The same thing, too, was kept in mind in selecting the times of subsequent observation. Notwithstanding this precaution, however, it would be well if some observer who has a large telescope should now re-examine the positions of these objects.

Researches in faint nebulæ and nebulous stars appearing likely to constitute a separate and interesting branch of the astronomy of the future, it has seemed to me that the astronomers engaged in this work may like to make a careful examination of some of the stars entered in my observing-book under the category of "suspected objects." The method I adopted of

[1] By David P. Todd, M.A., from the *Proceedings* of the American Academy of Arts and Sciences.

insuring re-observation of these objects was by the determination, not of their absolute, but only of their relative, positions, through the agency of the larger "finder" of the great telescope. This has an aperture of five inches, a power of thirty diameters, and a field of view of seventy-eight minutes of arc. Two diagrams were usually drawn in the book for each of these objects,—the one showing the relation of adjacent objects in the great telescope, and the other the configuration of the more conspicuous objects in the field of view of the finder. Adjacent to these "finder" diagrams are the settings,—to the nearest minute of arc in declination, and of time in right ascension,—as read from the large finding-circles, divided in black and white. The field of vew of the finder is crossed by two pairs of hair-lines, making a square of about twelve minutes on a side by their intersection at the centre. The diagrams in all cases represent the objects as seen with an inverting eye-piece. As the adjustment of the finder was occasionally verified, as well as the readings of the large circles, there should be no trouble in identifying any of these objects, notwithstanding the fact that no estimates of absolute magnitude were recorded. The relative magnitudes, while intended to be only approximate, are still shown with sufficient accuracy for the purpose of the research, and the diagrams are, in general, faithful tracings from the original memoranda.

[Mr. Todd transcribes the observing-book entire.]

PRIME MERIDIAN TIME[1]

ON the first day of the month, the President of the United States, in his message at the opening of Congress, referred to the International Meridian Conference lately convened in Washington, in the following words:—"The Conference concluded its labours on November 1, having with substantial unanimity agreed upon the meridian of Greenwich as the starting point whence longitude is to be computed through 180° eastward and westward, and upon the adoption for all purposes for which it may be found convenient of a Universal Day, which shall begin at midnight on the initial meredian, and whose hours shall be counted from zero up to twenty-four."

The Canadian Institute is peculiarly interested in this announcement. No society, literary or scientific, has taken a more important part in the initiation of the movement to reform our Time-system, of which the success is, to some extent, indicated in the President's words. It therefore appears to me fit and proper that I should recall to your attention the various steps which from time to time have been taken, so that we may possess a record of the events which have led to the now almost general recognition of the necessity for a new notation.

Six years ago on several occasions the meetings of the Institute were engaged in discussing the subject of Time-reckoning and the selection of a Prime Meridian common to all nations. Papers were read and arguments were advanced, with the view of showing the necessity of establishing a cosmopolitan or universal time, by which the events of history might be more accurately recorded, and which would respond to the more precise demands of science, and generally satisfy the requirements of modern civilisation. The *Proceedings* of the Institute for January and February, 1879, give at considerable length the views submitted and the suggestions offered to meet the new conditions of life. While on the one hand it was argued that the introduction of a comprehensive scheme by which time could be universally reckoned was highly desirable, it was equally maintained that the determination of a common Prime Meridian for the world was the key to its success, and that the establishment of such a meridian, as a zero, recognised by all nations, was the first important step demanded.
